That the electric light is and will be used, where a powerful light is desired—even in cities—is beyond doubt. It is and will be used for lighthouse service, fortifications, armies in action, manufactories, show rooms, open-air use, railroad depots, steamboats, mines, theaters, streets, etc. But in these uses of the electric light Mr. Edison does not claim to have made any advance. For these purposes the electric light is superior to all others and much cheaper, but for private houses, etc., where a powerful light cannot be used, and where a light easy to manage, safe, cheap, steady and sure, is requisite, we cannot agree with Mr. Edison, but think that it will yet be a long time before we shall see its introduction.

A great deal has been said about the difficulty of dividing the current, as if this were the important difficulty. In the old form of carbon-point lamps it is difficult to divide the current, because the resistance of the lamp is constantly varying, but in the lamps where a continuous strip is used to emit the light, no such difficulty is encountered. It is just as practicable to divide the electric light (as they say) as it is to operate any of the systems of telegraphy by which more than one message may be sent over one wire at once.

To sum up. A substitute for gas in the form of electricity must be a lamp, which is in intensity between five and twenty-five candles, is as steady, as durable, as easy to manage, cheap to make, and which can be supplied with the electricity at an expense considerably less than gas. Mr. Edison has succeeded in constructing a lamp which conforms to these conditions much more than any other lamp, but at the same time he has made a lamp which requires so much electricity in proportion to the amount of light given out, that its cost alone excludes the possibility of its taking the place of gas. Had he succeeded in reducing the cost to that of gas, the reasons for still preferring gas are very apparent. It would require a cost far below that of gas to insure its introduction.

Let us suppose a city of 500,000 inhabitants to be furnished with electric light from platinum lamps—say ten candles to each inhabitant. The aggregate amount of light would be 5,000,000 candles, and if only 100 candle-lights were obtained from one-horse power (which is much more than the paper lamp of Mr. Edison gives), it would then require 50,000 horse power to furnish this amount, leaving alone the energy consumed in its production and distribution, which would, without doubt, exceed this amount, with the best generating machine yet devised.

A word as to how Menlo Park is now illuminated by the electric light. There are two generating machines run by a seventy-horse power engine—now running at about twelve-horse power—to supply between fifty and sixty lamps, distributed in the houses and streets. It is claimed that each is equal to ten candles, gas being equal to about seventeen. The light is not white, or of a bluish tinge, as the electric lights now seen about New York, but yellowish and pleasant, very much like gas. It is almost perfectly steady, and is not dazzling. As there shown, it seems at first sight to be a success, but it must not be forgotten that the conditions under which the electric lighting is there carried on could not be better.

PERSONAL PARAGRAPHS.

King Humbert has been able to take a sleigh-ride at home for the first time in nine years, there having been no snow in Italy before since 1871.

The German Emperor has ordered that the fund of more than $60,000, collected on the occasion of his golden wedding, be exclusively devoted to the relief of the famine stricken Silesians.

Herijo Hendoelwoljo, reigning Prince of Surakarta, in Java, has arrived in Paris, in order to make the tour of Europe.

Rubenstein has gone to live in Italy on account of the failing health of his son.

Electricity at Sea.

Dec 22 1879

Mr. Edison at last is able to reward the patience of the public with the assurance that he has completed all the devices required for the adaptation of electricity to domestic purposes. If Mr. Edison can do commercially and on a large scale what he has succeeded in doing in his laboratory and on a small scale, the gas corporations, may as well begin to inquire whether there is an existence after death. For the purposes of navigation, however, it must be admitted, electricity needs yet a vast amount of adaptation. The steed, it is true, is caught, but it has yet to be tamed. At several places on the English coast, in France, in Russia and at the entrance to the Suez Canal, electricity has developed marked, if not fatal defects, as an illumination for lighthouses. The intense brilliancy of the light is calculated to deceive the seamen as to distances, and even to blind him as to the presence of immediate objects, such as ships and half-sunken rocks. From this cause the electric light has been displaced at Dungeness, the point on the English coast where it was first used. The same defect disqualifies the electric light for use on vessels at sea. On vessels that are large and steady enough for it to be used both on the bow and sides, it may prove serviceable. Were it to be used on the bow alone it would absolutely blind the navigator to the approach of vessels ahead, and enhance the chances of the very disaster which it was designed to avoid. It is to be hoped that navigation may yet share in the benefits of modern discoveries concerning electricity.

Evening Telegram

EDISON'S LATEST DISCOVERY.

Dec 22 1879

What Constitutes its Chief Value.

The latest report from Menlo Park is the announced discovery made by Mr. Edison of a new electric lamp, for which many startling things are claimed. The new light is produced from a little piece of paper heated to incandescence by an electric current which is made to pass through it. The piece of paper, "common bristol board"—two inches in length and one eighth of an inch in width, bent into the form of a horse-shoe, is heated in a furnace until nothing remains of it but a framework of carbon filaments. It is placed in a glass globe from which the air is extracted, and an electric current is passed through it.

Mr. Edison says that the results of his experiments show that the substance best adapted for carbonization and the giving out of incandescent light is paper.

The advantages claimed for the new light may be summed up as follows: The apparatus is ready to give out light that produces no deleterious gases—a pure, bright light without flame, without danger, requiring no matches to ignite it, free from all flickering, giving but little heat, contaminating no air, and a light that can be produced more cheaply than that from the cheapest oil.

Professor Ogden N. Rood, Professor of Physics in Columbia College, spoke to-day to a reporter of the EVENING POST to the following effect:

I believe that Mr. Edison is a great genius, but I also believe that he makes the mistake of being over-confident. I have not yet seen any experiment proving to me the properties of this new light, what it will do and what it will not do; but accepting the description which Mr. Edison furnishes, and admitting that the lamp works as claimed, it is not a discovery but an invention. No new principle has been discovered, but an ingenious invention of some importance has been made. Render carbon incandescent and you have nothing new. Incandescent carbon furnishes the light of nearly all the electric lights in use in the country.

Exhaust the air from the receiver in which the carbon is so as to extract the oxygen and you have accomplished something that has been accomplished in many previous cases. There have been methods in use to prevent the carbon of an electric light from being consumed by oxygen. In most electric lights the carbon points are separated, as the current passes the positive pole is eaten away particle by particle. Some particles give way more easily than others, and hence the flickering. Edison substitutes a continuous piece of carbon for his platinum wire. Now if this piece of carbon presents a uniform resistance to the current then scientists are rid of the regulators, which are expensive and very troublesome. This I consider the most important part of the invention.

HISTORY OF TWO DAYS.

Daily Graphic Dec 22 1879

Now for the annual winter howl about snow blocked streets. The job on Captain Williams's hands assumes huge proportions. He might read with interest Whittier's "Snow Bound."—Electrician Edison again "perfects" his electric light; no platinum wanted; carbon, red cotton thread fills the bill; and electrician Sawyer says he did the same thing some months ago.—The Fenans drew a large

Detroit Free Press Jan 4 1880

It has been proven conclusively that Edison's method of electric illumination is a ghastly failure. Sawyer, the New York electrician, has shown beyond a peradventure that he had a lamp of his own long before Edison set his burning, and that Edison is using some of his ideas. A London scientist has demonstrated that no vacuum can be secured for any practical purpose, and a brother scientist in Edinburgh shows that the carbon horseshoe has none of the elements of permanency. The Count Dumoncel, a French electrician, laughs at the whole scheme as chimerical. And, to crown all, the gas men of two hemispheres are unanimously agreed that the electric light is not, never has been and never will be practicable. Why Edison should persist, in the face of all this overwhelming testimony, in continuing his work, or why his lamps should persist in burning under the same discouraging circumstances, is a mystery. Perhaps it is due, in his case, to dogged obstinacy and in the case of the lamps to what Gail Hamilton once called the "total depravity of inanimate things."

WHAT WE HOPE FROM ELECTRIC LIGHTS.

The electric light is becoming more popular and more common in various quarters of the city, but not so common as it should be because of its want of divisibility. Much as it may be serviceable in the more populous thoroughfares, its greater utility will eventually be demonstrated in the more private and less frequented streets and among the poorer classes. The public is looking forward to the promised improvements which Edison foreshadows with a great deal of anxiety and hope, for upon those we must rely for the moral advantages which will be derived from its adoption. Its introduction is looked for to rid the city of a large part of the criminals by whom it is now infested, and to purify abandoned vicinities which have been literally transferred to the worst classes of immoral characters.

round the negative pole correspond to the negative features seen in Fig. 1.

LICHTENBERG'S FIGURES.

On a surface of pure resin shed with powder of sulphur and red lead the sparks give beautiful Lichtenberg figures of a different kind, which, when fixed on gummed paper, constitute valuable aids to the study of the electric discharge. These are illustrated by Figs. 3 and 4.

FIG. 5.

One remarks also that the movement leaving the positive pole envelops externally, like a sheaf of rockets, the negative movement (Figs. 3, 4, 5).

Often one perceives at the same time an interior flow of positive electricity round the line of the spark, besides the positive exterior enveloping current, and between the two the negative electric current, which seems as if sucked up (*aspirée*) by the positive current (Fig. 6). The negative

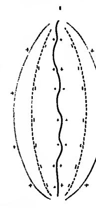

FIG. 6.

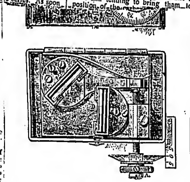
electricity of the ponderable matter which she takes along moves in an annular space formed by the electrified matter leaving the positive pole. This observation explains the effects of suction or ascension of water that we have obtained with currents of high tension. Do we not also in this phenomenon find the explanation of the uprise of water in the cloudy interior of a waterspout?

THE POCKET TELEMETER.

ALTHOUGH it is possible to measure the distances of accessible or inaccessible points without the aid of instruments, absolute accuracy is unobtainable by the processes used for this purpose; and hence arises the necessity of some instrument which shall give such measurements correctly and rapidly. The Telemeter invented, and recently improved, by Lieutenant Gaumet, fulfills in the highest degree, through its simplicity, the facility with which it can be used, and its small compass, all the conditions that an instrument of this nature should satisfy. This pocket telemeter is composed of two essential parts:

1. A system of two mirrors, D E (Figs. 1 and 2), arranged on a small metallic plate in such a way as to form an angle of 45° between them. One of them, D (Fig. 2), is stationary, and the other, E, is mounted on a movable radial bar. The angles of the mirror may thus be made to vary from 41° to 49°.

2. A very accurate micrometer screw with a half millimeter thread. The head of this screw is a circle divided at its circumference into a hundred parts. The screw itself works in a nut which is fastened to the metallic plate. A small rule is fixed to the edge of the latter, almost in contact with the edge of the circle, and serves as a datum reference. A spring, bearing on the extremity of the radial bar, maintains a permanent contact between the latter and the end of the screw. All these parts are arranged in a rectangular box, having in the back part a horizontal slit to serve as an eye-hole, and in front a rectangular opening for the entrance of the luminous rays emanating from the objects seen by double reflection. A tape line 10 meters in length, rolled around a bobbin, is affixed to the instrument and is used for measuring bases. The pocket telemeter is a direct application of the principle of double reflection. "When a luminous ray is reflected by two plane mirrors in succession in a plane perpendicular to their intersection, the angle formed



FIGS. 1 AND 2.—GAUMET'S POCKET TELEMETER. Perspective View, and Horizontal Projection, Actual Size.

3), places himself at A in such a way as to see at his right the point, C. The image of the point, C, appears placed directly beneath a natural or artificial signal, M, seen directly and situated on the direction perpendicular (or almost so) to A C. The angle, C A M, is a right angle every time that the two mirrors form an angle of 45°. When there happens to be no natural signal on the perpendicular direction, and it is impossible to locate an artificial one (man or rod) thereon, a neighboring point is chosen for this purpose; and, upon this point is brought the image, C', of the point, C, by turning the mirror at a small angle by means of the milled head of the screw.

(The error resulting from obliquity of the base is less than 1-200th of the distance when the inclination of the former does not exceed 8°.)

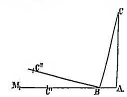


FIG. 3.

The image of the point, C, appearing in the direction of the point chosen, the observer measures off a base, A B, of 20 meters in the direction, A M. He then proceeds to the extreme end of the base and regards the signal anew. He then finds that the image of the point, C, no longer coincides with the signal, M, but is deflected to the right at a point, C'—C' B M being equal to A C B. In order to make them coincide again the movable mirror has to be turned at an angle equal to half of C' B M, or of A C B, which is equal to it. In the pocket telemeter, the angle of rotation of the mirror is measured by its tangent, and this measure is effected by means of the micrometer screw. The use of a like process gives a very close approximation; in fact, by means of the micrometer screw, a tangential displacement of 1-600th

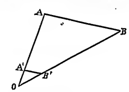

FIG. 4.

of a millimeter may be measured. When a coincidence between the signal and the point, C, has been effected at the end of the base line, the number of the division facing the able rule is read upon the head of the screw. The total number of divisions gives the measure of the tangent of the mirror's angle of rotation. This angle is half the angle, A C B, and the latter being always very small, the tangent of the angle, A C B, may be allowed, without perceptible error, to be double the tangent which measures the angle of rotation of the mirror.

Finally, for the purpose of doing away with all calcula-

tact-maker *h* will rest upon the stud *c*. The circuit is then complete between the two poles of the current represented by the two binding screws C and *a*. Supposing it to enter at the screw *c* it will pass through the magnet to the stud *c*, to the contact-maker *h*, and through the holder G to the outer carbon, thence through the inner carbon forming the luminous arc, and down the pillar E to the terminal *a*. The moment the current is established the magnet attracts the armature N, and places the outer carbon parallel to the inner one, towards which it had been inclined by the weight L, so as to facilitate the first flow of the current. When the carbons are consumed (as shown by pair number 1) as far as the finger *k*, the rod K is released, and the spring *m* turns it outward, removing the finger *f* from its spring *f*, which rises and removes the pin *g* from contact with the stop-piece *d*; the spring M then causes the lamp to revolve until stopped by the next pin *g*, and so on for the whole series. ARBORESCENT ELECTRIC DISCHARGES.

In former numbers of the *Telegraphic Journal* we have illustrated the interesting experiments of M. Gaston Planté on the form of the sparks obtained from his rheostatic machine

Sc. Am. Dec 20 1879

Fig. 1.

chine of 80 condensers under various conditions. More of these have recently been published by him in the second part of his work on "Recherches sur l'Electricité," and we are now enabled by his courtesy to place before our readers the most novel of them.

ARBORESCENCES.

When the poles of the machine are laid on a plate of insulating matter sprinkled with powder of sulphur the sparks are much elongated, and they also present tree-like figures when the excess of sulphur is raised by slight shocks given

Fig. 2

to the plate. Fig. 1 shows one of these figures, full size, obtained from a spark 0·15 meter long.

These effects explain the patterns of vegetation sometimes seen on persons struck by lightning; they are merely the branching of the lightning track.

Fig. 2 represents the furrow produced in the sulphur by a spark before giving the shocks which cause the arborescences. It will be observed that the width of the furrow is greater on the side of the positive pole. On the rays round the positive pole the sulphur is heaped up, while the traces round the negative pole correspond to the negative features seen in Fig. 1.

LICHTENBERG'S FIGURES.

On a surface of pure resin shed with powder of sulphur and red lead the sparks give beautiful Lichtenberg figures of a different kind, which, when fixed on gummed paper, constitute valuable aids to the study of the electric discharge. These are illustrated by Figs. 3 and 4.

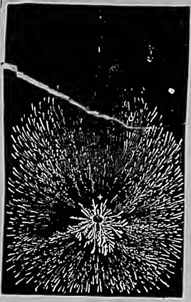

Fig. 3.

The difference between the effect produced by the brush discharge and sparks is very marked.

When the distance between the points of the exciter is too great for the spark to pass, and a brush discharge only appears, the electric movement of the ponderable matter leaving the negative pole, manifested by the red lead which adheres to the resin, does not extend to the positive pole. This last pole only presents traces of red dust in the middle of the crown of sulphur, with diverging rays, which surrounds it (Fig. 3).

But if the spark has passed, this crown is open and the interior is filled with red lead powder, showing that the electric movement leaving the negative pole extends even to the positive pole (Fig. 4).

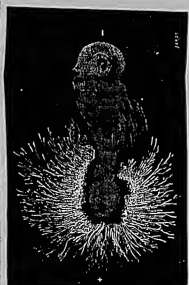

Fig. 4.

In the case of the spark the distribution of negative electricity presents a curious crab-shaped appearance (owl-shaped would, we think, be a better term); in the case of the brush it resembles more or less the form of a polyp having its tentacles directed toward the positive pole without attaining to it.

On the other hand, when the spark passes one recognizes sometimes, by the traces of sulphur round the negative pole.

29

tact-maker h will rest upon the stud c. The circuit is then complete between the two poles of the current represented by the two binding screws C and a. Supposing it to enter at the screw c it will pass through the magnet to the stud c, to the contact-maker h, and through the holder G to the outer carbon, thence through the inner carbon forming the luminous arc, and down the pillar E to the terminal a. The moment the current is established the magnet attracts the armature N, and places the outer carbon parallel to the inner one, towards which it had been inclined by the weight L, so as to facilitate the first flow of the current. When the carbons are consumed (as shown by pair number 1) as far as the finger k, the rod K is released, and the spring m turns it outward, removing the finger f from its spring f, which rises and removes the pin g from contact with the stop-piece d; the spring M then causes the lamp to revolve until stopped by the next pin g, and so on for the whole series. As soon as the rod K turns a contact-maker n at the bottom thereof is caused to bear against the bracket H, and so makes the circuit complete, whilst diverting it from the carbons. It will be seen from the foregoing description that although the current is diverted from the carbons by the contact-maker n it still passes through the magnet, and continues to attract the armature, opposing the revolution of the lamp. To obviate this the current may be caused to pass from the screw C to a pin q which secures one end of a flat spring r, the other end of which is raised a short distance from the face of the plate A. A pin s attached to the free end of this spring passes through the plate A, and directly underneath it is a contact-maker which leads to the magnet. As the lamp revolves the part n presses upon the spring r, and presses the pin down upon the contact-maker, thus rendering the circuit complete; as soon as the carbons are consumed the part n leaves the spring r, which then rises and leaves the contact-maker, thus interrupting the current until the armature has left the magnet, and another taken its place. Figs. 3 and 4 show another form of this lamp for four pairs of carbons.

Secondly, their invention consists in the use of an apparatus constructed in a similar manner to the lamps above described for regulating the transmission of currents to different circuits. For this purpose a self-acting or spring commutator may be employed, and its operation controlled by a series of triggers released at the required time by the consumption of a pair of carbons, one pair of carbons releasing one or more triggers either simultaneously or at different intervals as may be required. Such an apparatus may be so arranged as to require personal attention at considerable intervals only, and may be made to perform operations which at present are only performed with less regularity by hand.

LIGHTING OF THE BRITISH MUSEUM BY ELECTRICITY.

The lighting of the British Museum by the electric light has been commenced for the winter season, with great success. Two different systems are employed, the Reading-room itself being lighted by four lights of 5,000 candle-power each, produced by continuous currents, and the seven 400 candle lights, which are distributed over the entrance halls and the outside of the Museum, being connected in one circuit of about 1,200 yards length to an alternate current machine.

The regulators in the Reading-room are the invention of Messrs. Siemens and Halske, of Berlin, and are of a very simple construction, so that they can be easily managed even by inexperienced hands. As they are constructed to take carbons nineteen inches long, and as these are consumed at the rate of about three inches per hour, the light can be maintained for about six hours without the regulators being touched.

For the alternate currents other regulators are employed, which are actuated by two solenoids on a differential principle; one solenoid forming part of the main circuit and tending to separate the carbons, the other forming a shunt round the carbons and tending to bring them together. The position of the carbons depends, therefore, not on the strength of the current, but on the relative amount of electricity passing through each solenoid. By choosing suitable resistances for each coil an arc of a given resistance will always be maintained independent from the strength of current, and obviating the necessity of regulation after the lamps have left the hands of the makers.

These regulators are also so arranged that the going out of one, say through want of carbon, does not affect the burning of the other lights in the same circuit; and new carbons can be put in such a lamp in about half-a-minute, when it is ready to burn for another five hours.

The machines which supply electricity for the lights are placed in a shed behind the Museum, and are six in number, five being of the ordinary Siemens type (TELEGRAPHIC JOURNAL, November 15th, 1877), size B, and the other a Siemens-Alteneck alternating current machine (TELEGRAPHIC JOURNAL, September 1st, 1879). One of the machines is employed as the inductor for exciting the inducing magnets of the five others. The machines are driven by two 8 horse-power (nominal) steam engines, supplied by Messrs. Wallis and Steevens, of Basingstoke. These engines, which run very uniformly, are worked up to an indicated horse-power of 22, the steam pressure being 60 lbs. and the revolution per minute 120. The cylinders are 9½ in. diameter and 13 in. stroke. Messrs. Wallis and Steevens have just patented a new arrangement, which will enable the governors to maintain any particular rate of speed that may be desired, the adjustment being made gradually and without stopping the engine, thus fulfilling the condition so much desired by electricians, viz., the power to increase or diminish the normal speed of the engine at pleasure according as the lights require it, and then to maintain with perfect regularity the particular speed which is found to give the best light. The cylinders are steam-jacketed on Messrs. W. & S.'s improved plan of making the jacket and liner separate and fitting the liner into the jacket. The boilers are tested by hydraulic pressure to 150 lbs. per square inch, viz., double the highest working pressure of 75 lbs. to the inch. The fire-grate area and the amount of heating surface are unusually large. The engines are fitted with the makers now well-known Patent Annular-space Feed Water Heater, which delivers the feed water into the boiler at a temperature of

THE MORI-GRIFFIN LAMP.

Telegraphic News Nov 1, 1879

The advantages claimed for this lamp, which is the invention of Messrs. Mori and Griffin of Leeds, are its automatic action and arrangement of parts, and the doing away with personal attention except at long intervals, say 9, 12, or 16 hours, according to the number of candles or carbons the lamp is constructed to hold.

A great saving in wire is effected by the automatic commutator or switch being made a part of the lamp. It is possible by its means to switch off and re-light at will any one or more of the lamps in the circuit, without any perceptible change in the burning of the other lamps in the same circuit.

No injury can occur to the lamp after the whole of the carbons or candles are consumed, as the lamp moves forward on to a contact, thereby completing the circuit.

In figs. 1 and 2 we have illustrated a lamp for consuming eight pairs of carbons. This lamp is constructed so as to revolve upon a central spindle, and possesses advantages over the foregoing, inasmuch as the lighted carbons always occupy the same position, whilst the construction of the lamp is simpler and more mechanical. Fig. 1 is a sectional elevation, and fig. 2 is a plan view. A is a disc of hard wood, glass, or other suitable substance, and B is a circular box fixed underneath, in the middle of which is a binding screw a and a fixed spindle b. Another binding screw C is fixed to the under side of the disc, connected with which is one end of a coil of insulated wire forming the electro-magnet D, the other end of which wire is fixed to the stud c, which projects slightly above the upper face of the disc. On the surface of the disc is also a metal stop d, the use of which will be hereafter explained. E is a hollow metal tube, which fits upon the spindle b resting upon the bottom of the box, and free to revolve upon the said spindle. At the upper end of the tube is a circular table F, which carries a series of carbons, numbered 1 to 8, which are the inner carbons of each pair, the outer carbons being carried in holders G hinged to brackets H, screwed to the under side of a circular plate J, secured upon the hollow tube E. Between the brackets and the plate is a thickness of vulcanite e, and over the screws which secure the brackets to the plate are bone insulating eyelets. To each bracket H is secured a contact-maker h, that belonging to number 2 pair of carbons being shown resting upon the stud c. On the upper side of the plate J are a series of flat curved springs f, secured

Electrician

The New York Nation thinks the experiment at Menlo Park does not encourage an expectation of the early solution of the problem of how to use the production of the electric light, which is the only substantial problem relating to the subject left unsolved before." It declares, or surmises, perhaps, that Edison takes great care to keep his lamps at a low point of incandescence. If any or many of them were to be extinguished, the increased flow of the current would sooner or later destroy those remaining. Hence, during his exhibitions, his assistant narrowly watches the galvanometer, and when a light is removed, carefully shuts off a portion of the current, taking care to prevent it from flowing in excess of the quantity required. The Nation intimates that "this young gentleman," though not prominent, is the most important part of the exhibition. That objection, however, is so eminently Mr. Edison's affair, that outsiders must take it for what is worth. Perhaps he contemplates inventing an artificial young man, like a "governor" to a steam engine."

THE TEMPERATURE OF CARBONS GIVING THE ELECTRIC LIGHT.

Ia. Am. Engr. Nov 22 1879

The temperature of carbons giving the electric light has been examined by M. Rossetti, by means of a thermopile, the face of which is placed at a suitable distance to receive rays from a radiating surface of determinate size; the thermal effect being measured by a sensitive reflecting galvanometer. He comes to the conclusions that—1. The positive pole has higher temperature than the negative. 2. The temperatures vary according to the intensity of the current. 3. They are higher, the smaller the radiating surface, provided it comprises the extreme point. 4. In the negative pole the minimum temperature was 1910° Cent., with a large radiating surface of small brilliancy; the maximum 2532° Cent., the radiating surface being half the preceding. 5. For the positive pole the minimum temperature was 2312°, the carbon being large; the maximum 3200°, with a thin carbon and small radiating surface.

"The Electric Light on Shipboard.—A Liverpool contemporary says:—"If the electricians who are devoting themselves to the perfection of appliances for utilising electricity as an illuminating agent have not accomplished all that they promised, they have developed this system of lighting much further than many people could be induced to credit. The lighting of the Picton Reading Room by means of electricity illustrates what may be accomplished in a large apartment, though here the original intention of illuminating the place by the reflection of the light, rather than by the light itself, has not yet been carried out. However, we suppose the committee are anxious to move cautiously in the matter, with a view to acquire experience which may be useful in other corporate buildings. Experiments are being conducted on both sea and land. The first step in the direction of electric lighting on shipboard was taken by the Pacific Steam Navigation Company, as announced a short time back. The light was used experimentally in the saloon of the new steamship *Mendoza*, belonging to that company, as she came round to Liverpool from Glasgow, a simple Gramme machine and service lamp, used for the illumination of Messrs. Napier Bros.' boiler-shop, being utilised for the occasion. The satisfactory result of this trial is now manifested by the fact that the Pacific Company have entrusted the British Electric Light Company with the work of fitting two electric lights, produced by means of Blandy's patent, from one small Gramme machine, in the saloon of the *Mendoza*. This ship is intended for service on the West Coast of South America, and is a beautiful vessel, specially designed and adapted for the particular trade for which she was built. The saloon is large and tastefully decorated, as already described. The particular method of applying the light, which has been selected by Mr. Radcliffe Ward, the electrical engineer to the British Electric Light Company, is by reflection from special reflectors in the ceiling of the saloon. The result is a beautifully diffused soft light that effectively exhibits the tasteful painting of the saloon panels. On Saturday last, several of the directors of the Pacific Steam Navigation Company, with some friends, had lunch on board. The shutters of the saloon were closed, and the electric light was used to illuminate the apartment throughout lunch, with the exception of a few minutes when it was turned out to illustrate the marvellous difference between it and the usual candle light, which involves about double the expense of the electric light. The candles made a very weak display. Discussion of the merits of the light is almost superfluous. The success of the light on board the *Mendoza* will doubtless lead to the adoption of similar lighting on board all the principal ocean steamships before long. The illumination of the state-rooms by the incandescent system, in one form or another, is likely to be accomplished ere long. The boon to passengers of being able to turn on a bright settled light at desire will be very great. In this case the light will be placed in globes hermetically sealed. It will be seen that the electricians are doing their best to justify the hopes they raised a little time back."

REYNIER'S NEW INCANDESCENT ELECTRIC LAMP.

As is well known, the principle of Mr. Reynier's electric lamp consists in making a slender carbon rod incandescent by means of an electric current that traverses a limited part of the rod, between a lead contact and carbon holder in which the carbon glides forward.

Mr. Reynier has continually simplified his lamp until he has arrived at the novel arrangement shown in the annexed cuts.

The carbon, C, is pushed in the direction of the arrow by

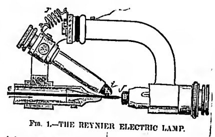

FIG. 1.—THE REYNIER ELECTRIC LAMP.

some suitable mechanism, and abuts against the end contact, B; the contact is mounted in the end of a lever held against the carbon, C, by a spring, r, and confines the incandescence of the carbon rod, C, to the space between i and j.

The end contact, B, is mounted in a carbon holder on a curved arm in the lower part of the lamp.

In order to introduce the carbon rod into the lamp the carbon holder is removed, the carbon, C, is placed into its tube, the carbon holder is replaced, and the lamp is ready for operation.

The incandescence shows itself, as we have said, between i and j, and varies in length from 0·16 to 0·31 of an inch. The light obtained is equal to that of 5 to 20 Carcel lamps, according to the intensity of the electric current and the length of the incandescent part of the carbon. With a pile

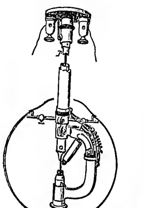

FIG. 2.—THE REYNIER ELECTRIC LAMP.

of 8 Bunsen plates (Ruhmkorff model) a light equal to about 12 Carcel lamps can be obtained.

If magneto electric machines are used, 3 to 5 lights, each equal to 8 to 14 Carcel lamps, can be obtained per horse power, thus giving a production of 30 to 40 Carcel lamps per horse power.

Mr. Reynier has devised several variations of his lamp, and actuates the carbon rod by means of a hydrostatic mechanism or by counterweights, a moving barrel, which operates in all positions, and the suspended apparatus, which is the most simple of all, and is shown in Fig. 2. In this case the movement of the carbon is obtained by the descent of the cylinder, p, which acts directly upon the end of the carbon.—*La Nature.*

DR. MOTT'S ELECTRIC OBJECTIONS ANSWERED.

Herald Jan 6

NEW YORK, Jan. 2, 1880.

TO THE EDITOR OF THE HERALD:—

In yesterday's HERALD Henry A. Mott, Jr., Ph. D., presents ten objections to the use of electricity for domestic illumination. As these objections include those which are generally current I beg space for a brief reply, though some of them have already found satisfactory answers in the reports and explanations of Edison's inventions, which have from time to time appeared in your columns:—

First—He objects that electricity cannot be stored and that therefore any breakage of the generating apparatus must interrupt the light, to which I reply that from its simplicity of construction the electric apparatus would be but slightly liable to derangement. Interruptions would probably be less troublesome than those which occur from breakage or leakage of gas pipes. It will, perhaps, be found expedient that each generator should have a duplicate or a galvanic battery so arranged as to be automatically set in action by the stoppage of the current.

Second—He assumes that with a given apparatus it will require nearly the same power to produce a small as a large amount of electricity. On the contrary, the magnetic resistance, in overcoming which most of the force is expended, can be graduated simply and easily in accordance with the required amount of illumination. Every one who has used a magneto-electric machine is familiar with the means of effecting this result.

Third—The cost of the electric light is asserted to be much greater than that of gas. This may be true of the imperfect appliances hitherto in use, but under Edison's system (though that system will doubtless be further improved) it is destined to be far more economical than any other known means of illumination, because the intense incandescence produced (as shown by Tyndall) gives origin to a larger amount of light, in proportion to the heat emitted, than any luminous body except the sun, the ratio being probably three times higher than that of a gas flame.

Fourth—The assertion that the current cannot be utilized beyond 500 feet is true only when the quantity is small or the conductors imperfect or inadequate. In practice, however, it will not be necessary to convey it very far from its source.

Fifth—Within certain limits the division of the material which is subjected to incandescence produces no great change in the total amount of light evolved. The statement that the Wallace machine gives but six lights to the horse power is misleading. If a current of this strength is used after Edison's method in six lamps each should give more light than "one hundred candles." It can certainly be divided very far beyond this.

Sixth and Seventh—If the strength of the current varies the light will fluctuate, as gaslight does under varying pressure, but every one who has tried both knows that the electric is by far the steadier light, being little affected by currents of air or by changes in atmospheric temperature.

Eighth—The objection that it will be expensive to distribute electricity from a main station seems extraordinary, in view of the fact that nothing is required but ordinary conducting wires, whose cost would be but a small fraction of that of such a system of tubing as is necessary to convey gas. To measure the supply to consumers simple registering electro-magnetic meters may be devised, which, like gas meters, may be made to record with perfect accuracy.

Ninth—This objection refers to the divisibility of the light, which has been already noticed (five).

Tenth—The objection that people will become moonstruck by the electric light (if seriously offered) suggests that possibly its author has experienced the effect of a malign influence of the kind, to the detriment of the mental equilibrium that should always be preserved by a Ph. D.

The electric light surpasses all others in purity and brilliancy, and it may be rendered absolutely safe, a most important consideration when we regard the vast number of disastrous fires which we own to our present means of illumination. Requiring no air to sustain it, it neither robs the atmosphere of our dwellings of its vital constituents nor loads it with a noxious effluvium to poison our lungs.

EZRA H. PULLING, M. D.

EDISON'S VACUUM APPARATUS.

With the exception of the peculiar carbon used by Mr. Edison in the construction of his lamps, there is nothing of more vital importance in the development of his system of electric illumination than the apparatus employed to exhaust the air from the little globes containing the carbon horseshoes, for upon the perfection of the vacuum depends the success of the lamp.

Since Otto Von Guericke invented the air-pump in 1650 it has been the subject of various modifications and improvements; but the most perfect forms of piston air-pump yet devised are incompetent to produce the degree of exhaustion demanded by modern experimenters.

In vacuum apparatus, as in most things connected with scientific investigation and experiment, the simplest means and methods prove the best. It seems that in the natural course of invention, simplicity is the latest feature attained. Air-pumps and vacuum apparatus form no exception to this general truth. The most recent as well as the most perfect air-pumps consist essentially of a glass tube and a column of mercury. Two forms of mercurial pump are used by Mr. Edison in removing the air from his lamp bulb; one for exhausting the greater volume of air, the other for perfecting the vacuum. The first is the invention of Geiss-

tubes that connects the two pumps, the Geissler tube, and the lamp bulbs. The connecting tube, g, extends over the scale, f, parallel to and near the gauge tube, f′.

To produce a vacuum in the bulbs, G, the pinch-cock on the rubber pipe, a, is opened so as to permit a rapid succession of drops, or a full stream of mercury to flow down the internal tube of the Sprengel pump, B. This stream of mercury, falling through the space between the internal tube and the lower end of the bulb, enters the long tube of the pump, and carries with it a certain quantity of air, which is discharged together with the mercury into the cup at the bottom. As this process is too slow for creating a vacuum from the beginning, while the Sprengel pump is still working, the Geissler pump, A, is brought into use for removing the greater portion of the air. To operate this pump, the stopcock, c, is first closed, the reservoir of mercury—connected with the pump by a rubber tube—is raised by the attendant, as represented in the cut, until mercury flows up the long pump tube, and filling the bulb, drives out the air before it through the discharge tube, and finally overflows through the tube, d, into the cup at the lower end of the tube. The mercury reservoir is then lowered until the two vertical columns of mercury break in the bend of the discharge tube, and the mercury in the pump is below the stopcock, c, the latter is then opened, and the mercury reservoir is lowered until the mercury in the pump will sink no farther. The stopcock, c, is then closed and the operation is repeated two or three times. The Sprengel pump, which has been in operation meanwhile, is now permitted to finish the work. As the vacuum becomes more and more perfect the mercury rises in the pump, and when the drops strike the mercury column, a sharp metallic click is heard, indicating that the atmospheric resistance to the falling metal is little or nothing. As fast as the mercury accumulates in sufficient quantities in the reservoir below, it is poured into the reservoir above.

Electric sparks from an induction coil are continually

Fig. 2.

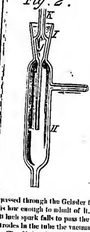

Fig. 3.

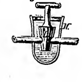

33

passed through the Geissler tube, D, as long as the vacuum is low enough to admit of it. Mr. Edison says that when a ... inch spark fails to pass the ⅛ inch space between the electrodes in the tube the vacuum is still coarse.

The McLeod gauge is relied on mainly for testing the perfection of the vacuum. This gauge is operated by simply raising the mercury reservoir connected with it until the gauge bulb is sealed off from the other parts of the apparatus, the mercury, as it rises, closing the connecting tube, g. The mercury reservoir is then raised still further, until the mercury will go no higher in the gauge tube, f′. Should the mercury rise to the end of the gauge tube it would indicate a perfect vacuum, but this is never attained. The quantity of air contained in the tube, f′, indicates exactly the proportion of the air in the apparatus to the capacity of the apparatus or air at its normal density. Another method of calculating the value of the vacuum is based upon the difference in the level of mercury in the two tubes in front of the scale, f.

Mr. Edison informs us that the vacuum in his lamps is so nearly perfect that only a millionth of the original volume of air remains.

It is obvious that the Sprengel and Geissler pumps must be longer than a barometer, to obtain the full effect of the falling column of mercury. All of the rigid parts of this apparatus are made of glass, and wherever there is a joint or a stop cock, it is sealed with mercury. Figure 2 shows the upper portion of the Sprengel pump in detail, and also gives a good idea of the manner of sealing the joints. The bulb, H, has a conical mouth, I, into which is fitted and ground the enlarged portion, J, of the mercury tube, K. The space in the mouth, I, above the enlarged part of the tube, K, is filled with mercury.

Figure 3 represents a mercury-sealed stop cock, L being the stop cock, entirely surrounded by mercury contained in the cup, M.

The lamp bulbs, G, are connected with the apparatus by a joint similar to that represented in figure 2. From time to time, while the air is being exhausted from the lamps, they are tested by connection with wires from the electrical generator. When the vacuum is practically complete, the

for information which any school geography or the nearest public library could furnish. He then goes on to describe conditions of Brazilian climate, productions, social customs, and the like, which make it impossible for many articles of American manufacture ever to find a market there, pointing out at the same time several lines of manufactures which, by proper management, might be sold largely in that part of the world.

A particularly suggestive and valuable part of the report will be found in the comparison made between the methods of German commercial agents and merchants and those of our own country. The mercantile training of the former embraces not only all the details of office work, but a thorough knowledge of geography and of the products of every land, of mercantile law, and of at least two languages besides their own. The first business of the German agent is to master the language of the people he is to trade with, if he has not already acquired it. Similar qualifications are the exception among the ambassadors of American trade. The majority of them have to employ an interpreter to make their business known, and the interpreter can rarely speak so as to compel attention and belief. Under such unfavorable conditions it is not surprising that American agents in Brazil are apt to be less successful than those of German

ler; the second, of Sprengel. The engraving shows the arrangement of these pumps in connection with the McLeod gauge, and other accessories.

Several sets of this apparatus are employed by Mr. Edison, and he has so far improved their construction and working as to enable the attendant to produce very high vacua in twenty-five minutes.

The Geissler pump, A, the Sprengel pump, B, and the McLeod gauge, C, are all connected with the socket that receives the lamp bulbs, through the bulb, E, which is partly filled with phosphorous anhydride—a powerful absorbent of moisture—and through the bulb, F, which contains gold leaf to absorb traces of mercurial vapor. Each set of apparatus is secured to a vertical board, behind which on a bracket near the top sets a reservoir of mercury, which supplies the Sprengel pump, B, through the flexible tube, a, and through a vertical glass tube, having at the top a trap, b, for receiving any air that may be carried by the mercury.

The Sprengel pump, E, consists of a glass tube about ⅛ inch in internal diameter and 36 inches in length, dipping at its lower end into mercury contained in the small vessel resting on the bracket, and having an overflow connected by a flexible tube with a mercury receiver. At the upper end of the ⅛-inch tube is formed a bulb, into which the mercury

Brunswick ... Jan 8/80

Electric Light.

It seems now to be an established fact that the electric light has at last been brought into practical use by the "wizard of Menlo Park." Since the announcement that the light and laboratory were ready for the inspection of visitors, a great many have availed themselves of the privilege, until the crowds became so large that all work had to be practically suspended. Among those who helped to swell the crowd Thursday evening were about one hundred and fifty-four from this city, and from what we can learn from them, the rush of incoming visitors continued until midnight, and the railroad company had extra trains running to accommodate the travel. The rush was so great and the visitors so disorderly (not those from this city) that the assistants were kept busy until a late hour guarding the scores of valuable and delicate instruments in the laboratory. A number of articles were broken and others stolen, among the rest a number of electric lamps, and, in consequence of all this, admission to the laboratory to see the lights will be, hereafter, only by special invitation or permit from the company's offices in New York, although the private dwellings and the street lamps will be kept burning nightly, so that those who wish to see the light will not be disappointed.

34

Wash Star ... Jan 9/80

WASHINGTON, Jan. 9.—Mr. Sawyer has entered a protest at the Patent Office against Mr. Edison being granted a patent for his horseshoe lamp, claiming [illegible] examination is made to discover if there is any infringement upon other inventions. If there has been [illegible] thorough examination of Edison's lamp will be made now than if Mr. Sawyer had not filed a protest.

The Electric Light at Sea.

The pioneer in the use of the electric light in passenger steamers, the Inman steamship City of Berlin, arrived at this port, October 14. Six electric lamps were employed, four in the main saloon and two in the steerage, each of 400 candle power. The passengers expressed themselves as highly delighted with the new method of illumination.

THE ELECTRIC LIGHT IN HULL.—At a town's meeting held at Hull on Monday night it was resolved to empower the corporation to apply to the next Parliament for provisional powers to introduce electric lighting into the town in consequence of the high price charged by the three gas companies.

EDISON'S WESTERN RIVAL.

Mail Jan 10th

A Young Inventor Said to Have a Practical Electric Light.

CINCINNATI, O., Jan. 9.—A young inventor named Edwards, of this city, has invented a method of producing the electric light which those who have examined it believe to be superior, in almost every respect, to the Edison method. Among those interested in the inventor and his schemes, are Messrs. A. D. Bullock, W. H. Eckert, of the Bell Telephone Company, Flameo Ball, Jr., and A. J. Hodder, and these gentlemen will supply the means necessary to perfect his invention.

So far nothing has been perfected except on paper, but those who have seen the plans of the inventor assert that if successful the result will be to throw the Edison light clean in the shade. The inventor, Edwards, is a young man who has devoted his life to the study of electric science.

PERFORATING GLASS BY ELECTRICITY.—A simple method of perforating glass with the electric spark is described by M. Fages in a recent number of *La Nature*. The apparatus required consists (1) of a rectangular plate of ebonite, its size, for a coil giving 12 ctm. sparks, about 18 ctm. by 12; (2) of a brass wire passing under the plate and having its pointed end bent up and penetrating through the plate (not further). This wire is connected with one of the poles of the coil. A few drops of olive oil are placed on the ebonite plate about the point, and the piece of glass to be perforated is superposed, care being taken not to imprison any bubbles of air. The olive oil perfectly accomplishes the object of insulating the wire. One has then only to bring down a wire from the outer pole of the coil, on the piece of glass, above the point of the lower wire, and pass the spark. By displacing the glass laterally, for successive sparks, it is easy to make a clean series of holes in a few seconds.

Manchester

Every part of life, if rightly taken, should be a stepping-stone for higher endeavour, of one kind if another be impossible. We can always remember what we cannot recall; and where we have fallen below we can resolve to rise yet higher, so that this temporary lapse may be forgotten. If we cannot—if we have created too great a ruin ever to build up again, and must henceforth be content with disgrace and disaster—then have we always the future perfect purification by perfect penitence to look to, and the time when all this shall be at an end; and the poor tired slave, bound to the dead body of his own mistakes, may lie down to rest undisturbed by the waking bell calling him to the day's weary toil.

EDISON'S LATEST ELECTRIC LIGHT.

It is somewhat strange that carbon, the only substance of any value for the contact surfaces of telephone transmitters, should also prove to be the only substance suited to the light-giving portion of electric lamps. The production of an electric light by the incandescence of platinum is, for the present at least, laid aside by Mr. Edison for the more promising and more satisfactory carbon. Not the carbon so familiarly known in connection with electric lighting, but a new article having different qualities, and remarkable both for the simplicity of the process by which it is made, and its efficiency as a light-giving body when raised to incandescence by the passage of an electrical current.

Sc. Am. Jan 10 1880

The discovery of this new form of carbon was partly accidental, but more the result of Mr. Edison's faculty of seizing upon the slightest suggestion and following it as long as it invites investigation.

The first carbon prepared by Mr. Edison for this purpose was formed of a thread enveloped in a paste made of lampblack and tar, and carbonized at a high temperature. This carbon thread, although not remarkably successful, gave sufficient encouragement to warrant further investigation in the same direction. After the trial of a number of other substances it was determined that the best of all was paper, simple plain paper, without lampblack or other applications. In making these carbons the quality of cardboard or paper known as Bristol-board is used.

The completed carbon is shown full size in Fig. 1; the blank from which it is made is shown full size in Fig. 2. It will be observed, by comparing Fig. 1 with Fig. 2, that the paper shrinks enormously during the process of carbonization.

The manufacture of these little carbon "horseshoes," as they are called at Mr. Edison's laboratory, is very simple. The paper blanks, after being cut by dies in the form shown in Fig. 2, are subjected to heat sufficiently strong to drive off by destructive distillation all volatile matters. The paper horseshoes thus prepared are placed with alternate layers of tissue paper in shallow iron boxes, and weighted down with thin plates of ordinary carbon. These boxes are closed by tight-fitting covers, and placed in a muffle, when they are raised to a high temperature, which is maintained for a considerable time. The only index of the completion of the process is the crackling of the oxide [illegible] iron boxes. [illegible] boxes and placed between [illegible] small pla[illegible] lises, a a, which are supported [illegible] thin platinum wires blown in the glass base and forming [illegible] electrodes. A portion of the glass base and the carbon [illegible] its supports are inclosed by a glass bulb, from which the [illegible] is so completely exhausted by means of a Sprengel [illegible] that only a millionth part of the original volume [illegible]ins.

[illegible] Edison has improved the Sprengel pump so that high [illegible] may be produced in 25 minutes instead of the 45 [illegible] consumed in the operation by some of our physicists. [illegible] pump is so nearly perfect that none of the tests to [illegible] lamps have been subjected so far, indicate the [illegible] of the slightest trace of air.

[illegible]ding his Sprengel pumps and other vacuum appar[illegible] Edison fortunately secured the services of an expert glass worker, who was formerly engaged in the laboratory of the famous Geissler, of Bonn.

The electrical resistance of the slender carbon horseshoe is 100 ohms, and, while the lamp shown in Fig. 3 is intended to afford a light equivalent to a single four foot gas jet, it may be forced to give a light equal to that of 8 or 10 such jets. We saw a single lamp of this kind giving a light that enabled us to read the SCIENTIFIC AMERICAN 100 feet away. This was certainly an extraordinary performance for a piece of carbon having a surface no larger than that shown in Fig. 1.

One of the most remarkable experiments connected with the exhibition of these lamps was that of connecting one of them with the main electrodes by means of a yard of No. 30 copper wire, no larger than a horse hair. The light was maintained without heating this very small conductor. Of course a wire of this size is too small to use in regular practice, but it strikingly exhibits the advantage of having a light-giving body of high resistance.

The carbon is very tough and flexible, and not liable to be broken or injured by jars. We saw one of the carbon horseshoes nearly straightened before it broke. The carbon not only withstands rough mechanical usage; it is also proof against injury by the sudden turning on and off of the electric current. One of these carbons has been subjected to the severe test of applying and removing the electric current a number of times equivalent to 30 years of actual daily use, and yet the carbon is not in the least impaired.

The horseshoe form of the carbon has a great advantage over the straight pencil or the voltaic arc, the light being more diffused, and therefore softer and mellower, casting no sharp black shadows, nor giving such an intense light as to be painful to the eyes. The light resembles that of a gas jet excepting in the matter of steadiness, the electric light being perfectly uniform and steady.

The lamps are connected in multiple arc, *i. e.*, the two wires leading from the electrical generator run parallel to each other, and the lamps are placed between and connected with each wire. As Mr. Edison has his circuit arranged it does not make the slightest difference, so far as the lamps are concerned, whether one or fifty of them are in use; it does make a difference, however, in the power consumed at the generator. The regulation of the current is reduced to the simple matter of varying the intensity of the magnetic field in which the armature of the generator revolves.

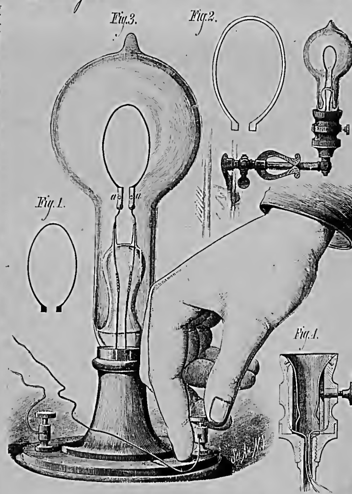
The entire lighting apparatus of a house, store, office, or factory, consists in the lamps and a few wires. There are no regulators, no complicated switches, no resistance coils to replace the lamps when the latter are not in use. The lamp, in its present form, is as simple as a candle, and, candle-like, it may be taken from its socket and replaced. This may be done while the current is on.

The construction of the socket which supports the lamp will be understood by reference to Fig. 4.

The lamp has attached to its electrodes slips of copper, which are bent upward against the sides of the glass, and touch two springs at opposite sides of the socket. One of these springs is connected with one of the electrical conductors; the other spring merely touches the copper strip, and does not form a part of the electrical conductor until it is touched by the thumb screw, *b*, this screw being connected with the second electrical conducting wire. To start the light it is only necessary to turn the screw, *b*, until it touches the spring. To stop the light the screw is turned in the reverse direction. From this it will be seen that the electric lamp is managed easier than a gas burner, as it requires neither lighting nor regulating.

On the evening of our visit to Mr. Edison's laboratory, he had more than thirty of these simple little lamps in operation, the current being supplied from one of his machines. Each lamp gives a clear, soft light equal to that of a four foot gas burner. These lamps had already been in continued operation for more than 48 hours, and they had seen altogether as much use as they would in 30 days of ordinary domestic or business service. The light certainly leaves nothing to be desired so far as its efficiency is concerned, and we are assured by Mr. Edison that, on the score of cheapness or economy, his system of illumination is far in advance of any other, not excepting gas at the cheapest rates. It seems that the subject of general electric lighting is now reduced to a mere question of time. If Mr. Edison's lamps withstand the test of time, he has unquestionably solved the vexed question and has produced what the world has long waited for; that is, an economical and practical system of electric lighting adapted to the wants of the masses.

The details given above were obtained by us direct from Mr. Edison and his assistants during a recent visit to the Menlo Park laboratory.



EDISON'S LATEST ELECTRIC LAMP.

36

ELECTRIC LIGHTING.

A FURTHER extension of the Jablochkoff system of electric lighting has this week been made from the central station at Charing Cross on the Thames Embankment. It will be remembered that rather more than twelve months ago that part of the Embankment between Westminster and Waterloo Bridges was lighted by 20 Jablochkoff lamps supplied by two Gramme machines, the motive power being one of Messrs. Ransomes, Sims, and Head's portable engines of 20 nominal horse power. After some months, an extension was made to Blackfriars Bridge, the number of lamps being increased to 40, and still more recently Waterloo Bridge was illuminated by ten lamps, which with five others fitted up in the board-room of the Board of Works, made the total number of lamps driven from the centre of Charing Cross no less than 55, and the length of conducting wires of over 18 miles. The latest addition was made on Monday last, on the afternoon of which day ten lamps, which had been fitted up in the Victoria Station of the Metropolitan Railway, were lighted. The space illuminated is 300 ft. long, 50 ft. wide, and 40 ft. high. The ten lights are distributed as follows: Over the down platform there are five lamps placed at equal distances apart; over the up platform there are four alternating with them, and there is one placed centrally against the bridge, crossing the station; all of these lamps are placed at a height of 13 ft. above the ground. The arrangement of the lamps is the same as that employed on the Embankment, and the candles are enclosed in opal globes 16in. in diameter. The ten lights are worked on the two spare circuits of the machines employed for illuminating Waterloo Bridge. In brilliancy and steadiness the light within the station leaves little to be desired, although the pulsations and changes of colour, which hitherto have been inseparable from the system, are apparent here as elsewhere. Of course any comparison between the

2652. "Improvements in electric lamps." CHARLES WILLIAM SIEMENS. (A communication from abroad, by Friedrich von Hefner Alteneck, of Berlin.) Dated July 1. 6d. Relates to a method of regulating electric lamps by the counteracting forces of two coils of different resistance, through one or other of which the lamp current was shunted. For this purpose the electric conductor in some part of its course to or from, or in the lamp, divides into two branches, the one leading through the coil of a solenoid or electro-magnet of high resistance, directly back to the external circuit, and the other leading through the coil of a solenoid or electro-magnet of lower resistance indirectly back to the external circuit through the carbons and the lamp. The cores of the two solenoids or the armatures of the two electro-magnets are connected by a lever to one of the carbon holders in such a manner that, when the one solenoid or electro-magnet, namely, that having the coil of high resistance, is excited, the movement of its core or armature causes the carbons to approach towards each other, and when the other solenoid or electro-magnet, namely, that having the coil of low resistance, is excited, the carbons are caused to recede from one another, and thus, when both are excited, the carbons are caused to take a position dependent on the relation of the two counteracting forces operating upon them, which position, by suitable adjustments, can be determined so as to produce the desired illuminating voltaic arc. (A full description of this lamp is published on page 412 of the present number of this JOURNAL.)

Platinum, after being rendered homogeneous under the vacuum treatment, is, Mr. Edison says, dissolved with great difficulty in aqua regia. Mr. Edison has submitted a specimen of vacuum-treated platinum to the action of boiling aqua regia for five days without its being dissolved.

Ironmonger Nov 22 1879

Edison's Last.—A telegram states that a public display of his new lamp has been going on for a week continuously without any failure.

... the Water Supply.—Rumour says that

EDISON appears to have solved the electric light question, at least, if we judge from the value of the stock of his electric light company, which has advanced from $300, at which it stood some months ago, to $5000 per share. Gas stocks have declined both in London and here, and other indications seem to confirm the substantial success of the new process.

Engineering & Mining Journal Dec 27

The antiquated method of manufacturing illuminating gas will soon be among the things of the past; for whether EDISON has actually succeeded in making electric light much cheaper than gas, as he asserts, or not, it is certain that he has solved many of the difficulties which had heretofore been deemed by the gas magnates as insuperable, and any remaining difficulties will soon disappear.

We welcome the advent of electric light as we welcome the cheap production of water-gas for heating and metallurgical purposes. These two great inventions will create a revolution in industry, and bring honor and credit to our American inventors.

Thomas Alvah Edison.

THE man most talked about at the present time appears to be Mr. Thomas Alvah Edison. An account of his latest invention appears in this issue, together with facts gained from personal observation at the Menlo Park Laboratory. Opinion is widely divided regarding Mr. Edison. In some quarters he is stigmatized as a fraud, a wilful deceiver of the public, a pseudo scientist, etc., etc. On the other hand, he is regarded by many as a scientist of high accomplishments, an inventor of such brilliant achievements as to render appropriate to him the figurative application of the term Wizard, etc., etc. Exaggeration seems the rule on both sides, in estimating this man's character. We shall depart from this rule, and accord to Mr. Edison the possession of a truly original inventive talent and much heterogeneous knowledge of scientific facts. We do not estimate him as a scientist in the full sense of that term, neither is he so far beyond all other inventors in originality of conception as to merit the name of Wizard. We regard the discoveries of, say, the late Professor Henry, considering the state of electrical science at their date, as far exceeding in merit anything Mr. Edison has ever accomplished. Mr. Edison is a rather more than ordinarily brilliant inventor, with a fragmentary knowledge of scientific facts; and we think that this is a just estimate—neither according too much nor too little. Fortunately for the exercise of his inventive talents, Mr. Edison has enjoyed the confidence and support of capitalists, who have supplied everything requisite for experiments and enabled him to concentrate upon, and apply to, invention and study, all the talent he possesses, un-

EDISON'S ELECTRIC LIGHT IN RAHWAY.—It having been stated to some of the papers that Mr. Edison purposed extending his wires to this city to test the electric light in our streets, Councilman Osborn, as chairman of the lamp committee, has written to him tendering the use of the vacant lamp-posts on such streets as he may desire for that purpose—subject to the approval of the Common Council.

EDISON'S LAST (?) ELECTRIC LIGHT.

In the fall of 1878, when the electric light excitement was at its height, the press was filled with sensational accounts of what Mr. Edison was about to do, and values were seriously disturbed. In accordance with our custom to treat all such questions carefully, honestly and intelligently, we submitted the matter to one of the highest scientific authorities on such subjects in this country, Prof. Henry Morton, President of Stevens Institute of Technology. His articles appearing in successive issues of this journal at the time, did much to enlighten the public and to check the previous sensational methods of treating this subject. When, therefore, a week ago, the *Herald* again startled the world with further claims in behalf of Mr. Edison we were naturally a little skeptical, and again applied to Prof. Morton for his views on these latest claims, which are set forth in the letter we now publish, and which we considered so important that we furnished it to the press in advance of its appearance in our columns. The postscript has been added since its publication in the daily papers, and was suggested by the comments it elicited.

To the Editor of THE SANITARY ENGINEER:

Having a sincere respect for Mr. Edison as an enthusiastic and ingenious investigator, I am sorry to see his name used by writers who evidently are quite ignorant of the subjects about which they treat in a way that will inseparably connect it with discreditable (because false) claims, evidently made in the interest of financial speculators.

No one can more thoroughly appreciate than I do the origioality of conception, the indefatigable patience and immense labor which have been involved in the series of experiments of which a sketch has been given in the New York *Herald* of Sunday the 21st; but when I see the conclusion of these, which every one acquainted with the subject will recognize as a conspicuous failure, trumpeted as a wonderful success, I have only left before me the two alternative conclusions that the writer of such matter must either be very ignorant, and the victim of deceit, or a conscious accomplice in what is nothing less than a fraud upon the public.

Such writing as this, in fact, has the melancholy result of placing Mr. Edison and his electric light in the same catagory with Mr. Keely and his "water motor," Mr. Payne and his "electric engine," Mr. Garey and his "magnetic motor," and others of the same class.

Against this I protest in behalf of true science and for the sake of Mr. Edison himself, who has done and is doing too much really good work to have his record defaced and his name discredited

863. "Electric lamps." E. P. ALEXANDER (communicated by J. C. Jamin, Paris). Dated ... 6d. ... describes Jamin's electric candle, consisting of two upright rods of carbon side by side with air between, as in Wilde's well-known candle, the arc forming at the top according to Ampere's law. The conducting wire is made to loop over the arc and divert the latter or draw it out to a point. Various arrangements of the arc and circuit are described. In two conducting wires are made to run parallel with the carbons till they turn off at a certain point at right angles to the latter. The arc therefore passes between the carbons at a point near this, and the carbons are burned into two parts. The upper parts of the two carbons being supported loosely in tubes will then gradually descend as they are consumed, while the lower parts remain practically unconsumed. By another plan a solenoid is placed opposite the arc of an ordinary electric lamp, to draw it out to a point against a piece of lime or other refractory body.

A NEW comic opera to be produced in Baltimore, America, bears the name of "The Electric Light." Some talented low comedian, a Yankee Lionel Brough or J. L. Toole could make excellent capital out of a burlesque of Edison and his wonderful lamp. Here is an opportunity for histrionic fame.

THE ELECTRIC LIGHT AGAIN!

FOR some little time past we have not heard a great deal of the electric light, with the exception of particulars from time to time of its successful use on the Thames Embankment and certain places elsewhere in the metropolis. It does not appear, however, that the gas companies are to be left in sole and undisputed possession of the field, seeing that a telegram from Philadelphia reminds us that the redoubtable Mr. Edison is still bent on demonstrating the superiority of his pet means of illumination. Not satisfied with having proved that platinum can be obtained in large quantities, instead of being the scarce metal we had always supposed, the eminent American experimentalist and inventor is reported to have now discovered an effective and cheap means of utilising the electric light as a substitute for gas for domestic uses. The telegram informs us that "after 15 months' experimenting Mr. Edison accidentally discovered that burnt paper is the best substance to use. He cuts from cardboard a narrow strip, shaped like an elongated miniature horseshoe. This is placed in a wrought-iron mould, which is heated slowly to a white heat, driving off all volatile portions of the paper, which is then gradually cooled. The charred remains of the horseshoe are taken carefully out and are placed upright in a little glass globe, the wires of the generating machine being attached at the end of the horseshoe. The air being exhausted from the globe, it is sealed, completing a lamp costing about 1s. This, it is claimed, will produce a bright, mellow light, without flicker or pulsation." These are, doubtless, somewhat vague and general particulars, but they certainly seem to show that Mr. Edison has at length hit upon about the cheapest and least weighty kind of carbon which could possibly be obtained. Whether he really and unfailingly performs the programme detailed above yet remains to be seen. Philosophy nowadays needs to be thoroughly practical, or it is liable to be counted as being of little worth. We had better, therefore, await further particulars before we dispose of our gas shares, clear out our stocks of chandeliers and burners

39

MR. EDISON'S NEW LAMP.

AN INVENTION OF GREAT PROMISE.

MENLO PARK ILLUMINATED—CARBON MADE INCANDESCENT IN A VACUUM—AN OLD IDEA NOW UTILIZED BY MEANS OF MODERN SCIENTIFIC APPARATUS—A GREAT STEP TAKEN IN ADVANCE.

Menlo Park, the little village at which Mr. T. A. Edison has established his shops, is now partially lighted at night with electric lamps of a new pattern, constructed within the last two or three weeks. The shops of Mr. Edison, three dwellings, and the street lamps along two or three roads are supplied with this new light, the total number of lights being so far forty-five; and new lamps are being made so as to increase the number in a few weeks to about 800. One of the lamps now in use has been lighted, day and night, for about seventeen days. The others have been used about two weeks.

For the first time, Mr. Edison allows the general public to inspect a lamp of his invention in actual use, and these new lights are freely exhibited every day, large numbers of people going out to Menlo Park every afternoon and evening to see them. They are lighted daily and put on public exhibition in order to develop defects and subject them to the practical test of every day use in order to discover if they really are what they seem to be to the inventor—a solution of the problem of household illumination by means of electricity.

The lamps are constructed on an old principle, which inventors have been trying to utilize for about forty years, and which Mr. William E. Sawyer of this city especially has been laboring diligently for the last two or three years to realize. A piece of carbon introduced into an electric circuit, and made incandescent in a vacuum, is the whole principle. The secret of Mr. Edison's apparent success is that he has been able to obtain an almost perfect vacuum, the best ever known, and to seal up his lamp in a way which positively and absolutely forbids the reëntrance of the air. The defects of the lamp are not yet fully understood, but it is being subjected to a rigorous test, and its weak points will soon be known, if it has any.

The steps which led up to the present invention are interesting, and will explain the principle on which the lamp is founded better than any formal description.

THE LABORS OF KING, KONN, SAWYER AND EDISON—THE PLATINUM LAMP THROWN ASIDE—A LUCKY SUGGESTION, OBTAINED BY ACCIDENT, FOLLOWED UP WITH ENERGY AND INTELLIGENCE.

The main idea of the new Edison lamp was thought of about forty years ago. An American electrician by the name of King attempted to utilize it in 1845. He invented a lamp wherein a glass globe was employed from which the air had been exhausted with an air pump. Inside of it was placed a piece of carbon or platinum, introduced into an electric circuit, and made incandescent by means of a strong current. Mr. King gave the gas companies in America a great shock. His invention was regarded as "an unfortunate discovery." He took it to England and created a sensation there also for a short time. He might have revolutionized the lighting of dwellings with it could he have maintained a good vacuum, when a carbon burner was used, or could he have regulated his current, when platinum was employed. He could do neither, and his light passed out of existence in the course of a very few years.

De Changy, a Frenchman, took up the idea in 1857 and congratulated the world promptly in a public manner on the success of his efforts, but he made a failure of it after all, and accomplished nothing. He had the same trouble as King.

Latterly, two men named Lodyguine and Konn, have taken up the idea in Russia. They have produced a lamp in which carbon is used in a vacuum, and have succeeded, within two or three years, in introducing it into several European warehouses and shops. The carbons burn out in a day or two and the lamps have to be replaced, but the light is so pure, strong and steady, and it is so absolutely free from fumes or products of combustion, that it is preferred to gas in certain establishments. It is costly, however, and has never come into general use.

Two or three years ago Mr. W. E. Sawyer, of this city, took up the idea, and last year he began to exhibit, at his little shop on Walker-st., a lamp very much superior to anything ever before produced. Mr. Sawyer employed a straight glass tube, about a foot long and two inches in diameter, closed at the upper end, and sealed at the other into a brass base. At first a slender pencil of carbon and, later, bent into the form of a horseshoe, and held between two stout pieces of carbon, was used, this part of the lamp being supported on heavy collars of copper, which conducted the current. Afterward a straight pencil of carbon, half an inch long, held between two large pieces of carbon, was employed. The tube was filled with nitrogen gas and sealed. By means of a switch of Mr. Sawyer's own invention, the current of electricity was regulated in quantity, and the light could be turned up and down exactly like gas. The light was equal to four or five gas jets, and was as pure, mellow and brilliant as the sunshine, which it resembled. The light produced by this lamp was fit for any dwelling, and it excited such great interest that Mr. Hugh McCulloch and other gentlemen of high standing formed a company to supply Mr. Sawyer with the means required to go on with his experiments. The drawbacks of the lamp were, first, that it was large and clumsy and not a desirable addition to the furniture of a tasteful apartment, and, secondly, that the carbons could not always be depended upon. The lamps would grow warm, and in cooling the sealing material would frequently crack, admitting the air, and promptly burning the carbon the next time it was lighted. It was found very difficult to get rid of every trace of oxygen. So long as any remained, mixed with the nitrogen, it was impossible to prevent the combustion of the carbon. Frequently it was found that there was enough air left in the carbon to destroy it in a short time. It may be said that Mr. Sawyer has continued his experiments diligently, and is still going on with them at the present time. He has a new lamp now, which he guarantees to burn 500 hours, but he has not been able to produce a perfect vacuum in his glass globe yet, or to exclude the oxygen completely from his nitrogen.

MR. EDISON TRIES PLATINUM.

Mr. Edison took up the problem of the electric light a little over a year ago. Like Sawyer, he made use from the beginning of the well-known law of Ohm for the subdivision of the electric current. In passing a current from a heavy main wire to a number of equal branches, the current is exactly subdivided according to the number of branches. Mr. Edison saw that he could divide the power of his current sufficiently to maintain any number of small lights, 10,000 or any other number, on one circuit, provided that a good lamp could be made to give out the light.

He tried the experiment first of using a wire of hardened platinum. The startling announcement, made in his behalf, in September, a year ago, that he had solved the whole problem with his platinum lamp, is well remembered. In spite of that announcement, Mr. Edison has never been able to utilize the idea of a platinum burner, either in a vacuum or any other way. He tried the experiment of enclosing the platinum in a glass globe in a vacuum, and found it economical. The radiation of heat from the incandescent wire was less in a vacuum than in the open air, and the energy of the current was therefore saved for the purposes of light. But that did not obviate the fatal defects of his lamp, against which he has struggled in vain with all the energy of a strong nature for over a year.

Newark ... Jan 2 1880

MR. SAWYER SCEPTICAL.

HIS VIEWS IN REGARD TO THE PRACTICABILITY OF THE NEW EDISON LAMP.

Mr. W. E. Sawyer, of No. 78 Walker-st., in this city, who has made long and careful researches in the problem of the electric lamp, was found at his office yesterday busily engaged in the perfection of a new invention designed for illumination. He is very much interested in the new claims of Mr. Edison, and was quite willing to express his opinion in regard thereto. He said:

"The public has received from Menlo Park the following positive assertions: [1.] That Mr. Edison's new lamp consists of a horseshoe of carbon about two and one-half inches long, clamped in platinum holders, and hermetically sealed in a glass globe from which the air has been exhausted. [2.] That the horseshoe, consisting of carbonized bristol-board, is so tough and flexible that it can be twisted nearly half way round without breaking. [3.] That the horseshoe of carbon, no oxygen being present in the globe, will last an ordinary lifetime; that it has already been run over 100 hours without suffering deterioration. [4.] That the light from each lamp is about equal to an ordinary gas jet, or say ten or twelve candles. [5.] That no dynamo-machine known can generate sufficient electricity to destroy one of Mr. Edison's horseshoes. [6.] That the chief point of advantage in the new lamp is its high resistance—116 Ohms. There are other statements, but the foregoing cover the ground pretty thoroughly. Having, during the past three years, made the most complete series of experiments respecting electric lighting by incandescence that have probably ever been made, I am enabled to speak positively about many points that to those unfamiliar, or only partially familiar with the subject may seem plausible, or else correct when entirely wrong."

"First, then," asked the reporter, "what is your idea about the use of platinum for conducting wires?"

"The use of platinum as a holder for the incandescent carbon conductor," replied Mr. Sawyer, "is fatal to the durability of a lamp. Carbon only, of larger section than the incandescent carbon, can be employed, for the reason that at a white heat the carbon combines with the platinum to form the platinum carbide, and disintegration takes place with great rapidity. The same is true of any metal. I have welded carbon pencils to all shapes, and the best way to establish the connection of the incandescent carbon with its holders is to weld the two together. This I have done by first clamping the horseshoe to carbon holders, then inverting the lamp and immersing horse shoe and holders in any hydro-carbon, preferably pure olive oil; finally turning on a torrent of electricity, so that the horse-shoe is made intensely incandescent. With great violence the oil is decomposed, the hydrogen escaping, and the carbon being deposited, most rapidly, at the points of contact of the horse-shoe and its holders. The weld is so perfect that the horse-shoe will break anywhere else rather than at the joints.

"Mr. Edison's paper carbon is very much longer than yours, Mr. Sawyer?"

"Yes, and when a length of incandescent conductor of one-half inch is reached, the current can no longer be economically used, because to increase the size is to increase the radiating surface, and the short carbon can be made to give all the light desired, viz., from 25 to 250 candles."

"What do you think of the kind of carbon which Mr. Edison employs?"

"The denser, harder and more homogeneous the carbon, the tougher it is and the more durable the lamp, for the reason that the whole action of the current (that very action which produces light, an intense vibration of the atoms or molecules of the carbon, amounting to several hundred trillions of vibrations per second) is to disrupt and disintegrate the carbon. The carbon formed by the process discovered, in my experiments, is the only one thus far that offers hope of permanency—a fine pencil of carbon being immersed in olive oil or any hydro-carbon gas or liquid, and electrically heated as in the process of welding before described, whereby it is built up with carbon so hard and homogeneous that it may be polished like jet. As we descend from this we get less durable material, the order of durability being: a. Carbon deposited by electric action; b. The hardest retort carbon; c. The best artificial carbon; d. Hard coke; e. Dense charcoal (charcoal impregnated with syrup and the syrup carbonized); f. Willow, paper and other fine charcoal; g. Ordinary charcoal; h. Graphite. Mr. Edison's carbon belongs to the class e or f, and as carbon in all its forms is extremely brittle, his statement that his paper carbon is so tough and flexible that it can be twisted half-way round, &c., without breaking, is open to criticism. The best carbons of the charcoal order we have produced by impregnating with syrup the finest French willow charcoal, used by artists, and carbonizing the same, repeating this process a sufficient number of times. This is substantially the process of Peyret and of Gaudoin. In pencils of 1/8 inch diameter and 1/2 inch length, with perfect carbon connections, and in an atmosphere of pure nitrogen, not even the 1/100,000 of oxygen being present, these carbons will last as follows, under the action of the electric current: a. At a red heat, giving a light of perhaps half a candle, 100 to 200 hours; b. At between a red and a white heat, giving a light of 1 or 2 candles, 20 hours. c. At a white heat, light 4 candles, 5 hours. d. At true carbon incandescence, when the pencil has the bluish appearance of the sun, and gives a light of 25 or 30 to 250 candles, 20 to 5 minutes, or even less than 1 minute, disintegration then occurring very rapidly but no consumption taking place. The smaller the section of the pencil, the shorter its life. The larger the section, the more current required. The longer the pencil the more current required."

"Do you think that the horse-shoe lamps are liable to be injured by an accidental and sudden increase in the strength of the current?"

"When a carbon is in a high state of incandescence," replied Mr. Sawyer, "double the current invariably ruptures or disintegrates the carbon. If Mr. Edison will only bring the current necessary for ten of his lamps suddenly into one of them he will be surprised at the beautiful manner in which it will disappear. Experience has demonstrated that, within reasonable bounds, the less the resistance of an electrical circuit, which includes the resistance of the wires of the machine and that of the lamps outside of it, the less the power required for effective work. The arrangement of Mr. Edison's lamps in multiple circuit so as to lessen the external resistance where a large number of lamps are to be run is hazardous. In running 2,500 lamps by a single generator, the mean will be found in a square of fifty in series and fifty in multiple. This would make the external resistance of Mr. Edison's circuit 116 O, requiring an intensity of current that would give violent shocks to those who might by accident touch the conductors, and a most costly insulation of the main wires. To place less lamps in series and more in multiple is as hazardous as to go the other way, inasmuch as it would increase the chances of a short circuit extinguishing lamps in other series. No lamp can be practical unless of low resistance."

THE BRUSH ELECTRIC LIGHT.—On Tuesday evening a successful trial of the Brush system of electric lighting took place in the presence of a number of scientific gentlemen at the offices of the Anglo-American Electric Light Company, No. 74, Hatton Garden. This system is the invention of Mr. C. F. Brush, of the United States, where it is in extensive use, and is now being introduced into this country by the above-named company. The system embodies important improvements and advantages in the three essentials necessary for electric lighting, viz.:—The generator or dynamo electric machine, the lamps or carbon regulators, and the carbon. The Brush Dynamo Machines are made in several sizes, capable of operating from 1 to 16, or even more lights in a single circuit, which may be of 10 or 12 miles length if required. In construction the machines differ essentially from all others both in the armature, the arrangement of the field magnets, and the commutator, and the novel mode of connection, producing, it is stated, from a given amount of power, a larger available current than has hitherto been obtained from any other combination. At the same time the mechanical construction is such, that the wear and tear is reduced to a minimum. The current is continuous, and the results of the experiments were highly satisfactory. We reserve details of this latest development of electric lighting for our next issue.

41

WHY NOT AN ELECTRIC LIGHT?

Erie Gazette

There are those who dispute the claims of Edison to the discovery of electric illumination, who say that others have preceded him in the essentials, and that the whole thing is impracticable. But this kind of talk need not surprise Mr. Edison, nor need the envy of all the horde of scientific theorists keep him from going ahead with his wonderful evolvements. It is said that at the very time when Fulton was getting ready to run his steamboat on the Hudson river, this same class of conservative speculators, who called themselves scientists, proclaimed the impossibility of utilizing steam for the uses of locomotion or for any practical purpose. These old fogy croakers will always, we suppose, be blocking up the avenues of real scientific advancement and of frightening timid adventurers back into the old sloughs in which it is popular to wallow.

But we hope Edison will not be deterred from persevering in his noble work for mankind. Suppose his present plans fail when it comes to the pinch: it does not follow that the investigation need be pursued no further. Why cannot electricity, the most powerful of all of nature's known forces, be utilized? We believe it can, and will be—not only for lighting our houses and streets, but for all purposes where steam is now used. In fact the possibilities in the use of electricity seem so grand that the imagination cannot lead one but a short distance into the brilliant domain.

Go ahead, Mr. Edison. Light Menlo Park if you can. But whether you can or not, do not "give up the ship." The practical men of the world believe you are on the right road; thus encouraged, you can afford to let the theorists twist and deride.

New York Herald Dec 21

THE ELECTRIC LIGHT continues to draw pilgrims to the Edison shrine of Menlo Park, where the little horseshoes gleam on the nigh[tly]. The necessary steps for a general illumination there are in progress, but as the system is extended it can be seen nightly. A letter elsewhere details the immediate plans of the inventor, and pertinently recalls some features of the struggle coal gas went through for public recognition at the beginning of this century.

Dec 21

There seem to be doubts in various quarters as to Edison's ability to do all he says he can do with his electric light, though most of the doubts have a croaking sound. It is hardly reasonable to suppose that, by means of his invention, every telegraph pole will be made to at once blossom out and shine like a double-sun-power calcium light; but that the perfected lamp under discussion will do all that any lighting apparatus can, and even more, there is little or no reason to doubt.

SUPPLEMENT.

N.Y. Herald Dec 22 1879

house politicians and Assemblymen.

A Lucky Horseshoe.

Yesterday, December 21, was the winter solstice, when Phœbus Apollo, driving the solar chariot toward the Antarctic Pole, stays his weary steeds for a moment and poises himself for his joyous progress northward. It was also the day set apart in the church calendars for honoring the "doubting apostle" who required tangible evidence before he would believe the latest and greatest of the Christian miracles. The day thus devoted to the prototype of all sceptics coincides very appropriately with the moment when solar light and heat are at their apogee, when the darkness can be felt and almost cut with a knife.

St. Thomas gray, St. Thomas gray,
The longest night and the shortest day

should, if our chronology were a really scientific one, based upon the eternal fixity of astronomical facts, be the date of the new year; and indeed it is probable that our year was intended as an approximation to the true solar epoch, an intimate accuracy being prevented by the fact that the winter solstice occurs in the middle of a month instead of at the end. The philosophers of the French Revolution, in reforming their calendar, attained this object, except that they chose to make the year commence at the autumnal equinox (September 21) instead of the winter solstice, and in so doing they merely reverted to the ancient astronomical year of the Hebrews and the Chaldeans. There are many who believe that the rising of "the Sun of righteousness with healing in his wings" was expressly typified by the assignment of the birth of Christ to this moment of deepest darkness before dawn, when "Light, more light!" is the despairing cry heard from the abyss of cosmical gloom.

Be this as it may, the renewal of light and life dates from the winter solstice in the social world no less than in the astronomical year. Christmas and New Year's are close at hand, and henceforth we are in full saturnalia. Millions of kindly souls are now intent upon the selection of gifts with which they will gladden the hearts of children, friends and lovers. Many and mirthful are the legendary tales, the symbolic practices and the half credited superstitions connected with this period. Books of fairy lore are in especial request by young and old. Ornaments in the form of a horseshoe have ever been exceedingly popular, and this year, as never before, the fashion has set in this direction. It is well known that the horseshoe possesses the magic virtue of warding all evil from its favored possessor and of conciliating to his service the sprites and elves of field, forest and flood. What more appropriate New Year's gift, then, could the master wizard of our time make to his countrymen than a "lucky horseshoe," which should at the same time be a magic lamp more practically useful in this workday world than the perilous marvels wrought by Aladdin? What more wonderful fairy tale was ever invented by Arabian imagination than the simple chronicle which the HERALD presented to a sceptical generation on St. Thomas' Day of the triumphs achieved by "that marvellous boy, that sleepless soul," Thomas Alva Edison? The record of his fifteen months wrestling with the most hidden problems of the physical universe will forever render memorable the annals of the current year, which is so crowned by an invention "in its simplicity sublime." One of the strongest and most enduring things in the world proves to be the mere cinder of a scrap of paper. Henceforth a manual of fairy lore will be as indispensable to the scientific man as his rows of cyclopedias and technical dictionaries. The Wizard of Menlo Park, after

Harper's Jan 6

A Challenge to Edison.

Mr. W. E. Sawyer, of New York, is not yet done with Mr. Edison. He asserts that, statements of Edison and other witnesses to the contrary notwithstanding, the Menlo Park inventor cannot run one of his lamps at twelve-candle power for more than three hours. After thus bluntly giving the lie to a brother scientist Mr. Sawyer kindly invites Mr. Edison to a private residence in New York, presumably his own, where he proposes that the Jersey electrician shall show what he can do. A neater method of implying that Edison is an idiot could not possibly be devised. If Mr. Sawyer had never invented anything else this challenge would be sufficient proof of the deftness of his ingenuity. If Mr. Sawyer wishes to test an Edison burner or a number of them why does he not take some trusty watchers, go to Menlo Park and make observations? Perhaps Edison would keep up the illumination many hours extra for the sake of converting this doubting Thomas.

Mr. Edison will probably be the subject of many such letters before his system is in practical use throughout any large city. The best thing he can do with them is to burn them. A man who has on his hands such a gigantic enterprise as the electric light is claimed to be is under no obligations to waste a moment in giving points to a rival. Letters and criticisms will be written from all sorts of motives—some of them honest, others to help the gas stock market for a day or to bring desired capital to the coffers of some rival company, or even to bear Edison stock, so that the writers may buy some at a decline; still others will write mistakenly, because, although they never thought of the possibility of such a thing, they do not know all or exactly the same things that Edison does. Let the inventor stick to his laboratory, making his tests to the public only; then, if any one chooses to remain unconvinced, in spite of his eyes, he will not be missed from the crowd.

SKETCHES IN EDISON'S LABORATORY.
ILLUSTRATING THE MECHANISM EMPLOYED IN PRODUCING HIS ELECTRIC LIGHT.

Edison's latest electropyre, or electric burner, consists of a small cylinder of pure zircon, heated to whiteness by a surrounding coil of platino-iridium wire.

Edison's call for platinum for his electric lamp has been responded to with interest by Western "prospectors," and a crystalline vein of it has been found in a seam of talc in Santa Clara County, California. The schistose rock in which the talc is imbedded was found to be so hard, however, that the work of quarrying proved unprofitable. Prof. Stewart, nevertheless, thinks that with proper tools it might be made to pay. Drift platinum was once found along with gold in old diggings of Trinity and Humboldt Counties, and the same authority recommends search in that region.

Telegraphic Journal Apr 1 1879

1622. "Improvements in the means employed for producing electric light." RICHARD COMINGS THOMSON. Dated April 24 [illegible]. Relates to the electro[illegible] used in the production of the electric light, and consists in the employment either in a dry powdered, or a moistened and plastic state, of the carbon or carbonaceous material or composition usually made into pencils or sticks of carbon for the purpose. The advantage being that the supply of the carbon may be made practically continuous. (*Not proceeded with.*)

Gas stocks may weaken, but Electrician SAWYER stands like a stone wall. In a letter addressed to the editor of THE SUN, he renews his profession of unshaken incredulity in the alleged discoveries of Mr. EDISON. He concedes that Mr. EDISON is a "mechanical genius," but denies that he has any rightful claim to the title of electrician. Several of Mr. EDISON's alleged discoveries and improvements in electric lighting are fully covered, he says, by his own patents; the horseshoe lamp in particular is derided by Mr. SAWYER, who avers that he himself invented it, tested it over a year ago, discarded it as worthless, and because it was such an utter failure decided that it wouldn't pay to take out a patent on it. In short, Electrician SAWYER asserts that Mr. EDISON "has absolutely nothing that is new or valuable in electric lighting." Electrician SAWYER has an electric light of his own, however, which he promises to exhibit, "in practical household use," in this city next week.

The Sun [illegible] 1879

The locomotive electric light recently introduced in England for railway use, is said to operate satisfactorily. To a light six-horse power four-wheel locomotive a dynamo-electric machine is attached; any electric light can be used. When the engine is moving along the line, the electric machine rotates at its proper speed, and, when it is necessary to stop, in order that the light may be directed on some particular spot, the driving wheels are thrown out of gear by means of the disengaging handle attached to the pinion on the crank shaft, and the machine ceases to be locomotive, while the engine continues to move the dynamo machine at its proper velocity. The engine is furnished with sensitive governors, so that the speed of the dynamo [illegible] being very important in order to insure a bright and continuous light.

[illegible]

how wonderful it is! I understand it all now. You bottle up the light in these little globes and then sell it for so much a bottle! Isn't it nice?" Another intellectual visitor entertained a crowd of admiring friends by explaining at length how the little chalk telephones which abound in the laboratory furnished the electricity that gave out the electric light.

COOL REQUESTS.

The requests for lamps and horseshoe carbons are numbered by the thousands, and many of the visitors feel indignant when the assistants politely decline to take their proffered pay for the same, explaining that they are not for sale. The little globes of fire still continue burning in all their beauty, notwithstanding the predictions of the sceptics. The three hours' test which a rival electrician loudly dared Mr. Edison to make, proclaiming that only that length of time was necessary to prove the utter failure of the invention, has now grown into a test of 240 hours, and still the lamps are burning. The loop which "I" referred to three days ago as having been placed under water and made to give light in that position still remains submerged, and no change has occurred in the light, thus suggesting an important aid for submarine divers in their work. Several thousand people have now seen the light, and Mr. Edison feels satisfied that he has practically answered the sceptics.

THE QUESTION OF COST.

The exact cost of the new light the inventor has not made public, but it is characteristically summed up in one answer which he was overheard to give an inquirer:

"After the electric light goes into general use," said he, "none but the extravagant will burn tallow candles."

Edison's Triumph.

N.Y. Herald Jan 3 1879

As might have been expected, the magnificent success of Thomas Alva Edison in developing his electric light, as made known in Sunday's HERALD, has had the instantaneous effect of calling forth the carping criticisms of rival inventors. A paragraph in one of the city dailies yesterday referred to Edison's invention as a mere modification of the Sawyer-Man patent, and another of our contemporaries, the Sun, contains an ill-natured fling by Mr. W. E. Sawyer, in which he challenges the well-earned reputation of our great inventor in respect to his quadruplex telegraph and his carbon telephone. It is rather late in the day to discuss these points, and we are satisfied to leave them to the mature judgment of the present generation of scientists. But Mr. Sawyer proceeds to formulate a series of eight challenges to Mr. Edison, offering one hundred dollars premium for a successful answer to any one of them. They cover pretty nearly all the points presented as the distinctive features of Mr. Edison's invention, and if he were so disposed he might doubtless win eight hundred dollars by merely demonstrating them to committees of Mr. Sawyer's friends.

We do not, however, think it necessary in this year of grace 1879 for any one seriously to discuss a question of comparative originality as between Thomas Alva Edison and W. E. Sawyer. We say this without disparaging the problematical laurels of the latter in his own sphere as an inventor, but we would counsel him not to try conclusions with the "Wizard of Menlo Park." All great inventors have had their rivals and their detractors. What will the men of the twentieth century say if perchance they learn from some dog-eared volume that the greatest invention of the greatest inventor of all time was challenged by one W. E. Sawyer? Let Mr. Sawyer demonstrate his own inventions as satisfactorily as Mr. Edison and the world will then listen to him.

As compared with such carping criticism the generous commendations of Mr. Richard A. Proctor, printed in yesterday's HERALD, are refreshing to the generous mind, and the letter which we to-day print from Mr. E. J. Mallett, Jr., is a further testimony from the pen of a thoroughly competent scientist, who has himself experimented in a most interesting manner with the same wonderful element, carbon, which has yielded to Mr. Edison his last and greatest triumph. If any one is authorized to contest with Edison the palm of originality, as a carbonographer it would seem to be our correspondent, Mr. Mallett; but his letter, instead of filing a bill of complaint, contains a generous appreciation of the merits of his fellow physicist. His experiments with platinum chloride form a distinct addition to the sum of knowledge in this obscure branch of metallurgy and entitle him to rank as a discoverer. The differing attitude of Messrs. Mallett and Sawyer in this respect is deserving of notice, and the public will find no difficulty in awarding the premium for genuine science, fine insight and fellowship.

EDISON'S LIGHT.

A VISIT BY A WELL-KNOWN PHILADELPHIAN TO THE LABORATORY.

Mr. Henry Bentley in Company With William Leatham Bright and Engineer Joseph John Tyler Discourses Some New Uses for the Wonder.

Philadelphia News Jan 7

Columns and columns have appeared in the newspapers regarding Edison's electric light, and the subject might well seem written out, at least until Edison gives to the world figures concerning what the cost will be. However, there was a visitor at Menlo Park Monday who wished to investigate the light and with whom the question of the cost as compared with gas is a matter of small moment. This gentleman was Mr. Joseph John Tylor, a noted English engineer. He was accompanied by Mr. William Leatham Bright, the son of John Bright, M. P., and Mr. Henry Bentley, president of the Philadelphia Local Telegraph Company. Mr. Tylor and Mr. Bright have been travelling in this country since August last. Mr. Bright, who is a manufacturer, having a mill at Rochdale, England, employing over 2,000 operatives, wished to see if Edison's light could be used in his works, he having tried all the other electric lights and found them impracticable. Mr. Tylor, who is largely interested in coal mines in Wales, and who is an authority in mining matters, desired to investigate Edison's light to find whether it would not be practical to use it in coal mines and prevent the terrible loss of life which occurs when the fire-damp is ignited by the miners' lamps. Both gentlemen examined the light, spending Monday afternoon and evening in the work, and expressed themselves as perfectly satisfied that each had found what he had been seeking for.

"The question of lighting mines by electricity," said Mr. Bentley this morning, "is not a new one, but no means have hitherto been devised that would accomplish the purpose. The Edison light, however, bids fair to overcome the difficulties, and if it is brought into use there will be no more of the terrible catastrophes in mines. The ordinary electric light formed by the combustion of carbon rods would be as dangerous in a mine as an ordinary flame. But not so with Edison's. His light comes not from combustion, but from the heating of paper horseshoes (charred Bristol board) by the passage of electricity through them until they glow at a white heat. To prevent the combustion of the paper horseshoes and to make the lamps permanent, they are enclosed in a glass globe or bulb, from which the air is exhausted and a vacuum formed. Should the glass be broken while the light is burning the passage of air into the globe would, on the instant, cause the destruction of the paper horseshoe and there would be no light, not even a spark. From this it will be seen that the lamp is practicable for use in mines, and that it will prove one of the greatest boons ever presented to mankind. There will be no loss of life from the explosion of the dreaded fire-damp—at least from the miners' lamps; the work can be carried on in light instead of semi-darkness, and there will be a great saving of life from the latter fact alone. Hundreds of men are killed annually in the coal mines of England of whose deaths the public hear nothing, and that is by being run over by the cars in the dark tunnels. With Edison's light will come a new order of things. Wires will be run into the mines and lamps placed wherever required, so that the dark caves will be as light as day. Then other lamps can be carried about by the miners, connection being made to the main wires by means of flexible conductors. There will be no danger at all from their use. As explained the breaking of the glass globe of the lamp instantly destroying the light, and when the lamps are intact of course no gas can enter as they all are hermetically sealed. Mr. Tylor was perfectly enraptured by Edison's light and intends upon his return to England to lay the subject before the Royal Institute, of which he is a prominent member. He says that the excitement in England over the electric light question is intense. Mr. Bright was equally pleased with the light. He has tried every other system, but without success. The ordinary electric light was found impracticable, simply because it is too powerful. The workmen in his mills after once looking at the light could not see the threads in the looms for some minutes afterward. Various devices for modifying the light by means of reflectors were tried, but found not to be satisfactory.

Mr. Bentley, while talking to a NEWS reporter, told of different experiments the visitors made with Edison's lamps. One was to plunge the lamp, after the glass had become heated, into a jar of water, letting it remain there. It was there when Mr. Bentley left, glowing as brightly as ever, and this, he says, suggests another use for the lamp. With an insulated conductor it can be taken down under water and will not be affected. It will be of as much use to the diver into watery depths as to the miner delving into coal seams. "What a field of discovery," continued Mr. Bentley, "will it open to the naturalist and to the seeker after the mysteries of the sea. In Jules Verne's "Twenty Thousand Leagues Under the Sea," the characters in that wonderful fiction are represented as walking on the bed of the sea with electric lights in their hands and breathing air from a holder which they carry on their backs. The first part of this idea is now realized, and who can tell but that the other will follow in time. Edison's lamp is entirely practicable for strolling through submerged pleasure grounds, the length of the walk depending on the length of the wire running from the lamp to the generator situated on board a vessel, air, of course, being pumped to the diver in the usual way."

HEINRICHS' ELECTRIC LAMP.

43

Telegraphic Journal Oct 1 1879

ON Tuesday evening, the 10th ult., an exhibition of one of Mr. Heinrichs' lamps (see TELEGRAPHIC JOURNAL, 15th September) took place at 86, Gray's Inn Road, upon which occasion a number of gentlemen were invited, all of whom take an interest in electric lighting.

The exhibition commenced at eight o'clock, when about thirty gentlemen were present, among whom were Lord Lindsay, M.P., Mr. Spottiswoode, F.R.S., Mr. S. Wells, Mr. E. Cox, Mr. F. Flower, and Mr. J. Ashby.

The lamp was suspended in the open air, and during the evening was raised to an elevation of sixty feet. The current was supplied to the lamp from a single current dynamo-machine of 1,200 to 1,800 candle power. The light in the first instance was not quite as satisfactory as the inventor intended it should be, but after a short time it became very steady, and produced a most brilliant effect, the high elevation at which the lamp was placed showing this to great advantage. Mr. Heinrichs then showed, by quick interruptions of the current, that the lamp was always instantaneously re-lighted, and during the whole evening, up to ten o'clock, the regulating apparatus acted perfectly, which may be taken as a fair proof of the practicability of the step-by-step feeding arrangement (see TELEGRAPHIC JOURNAL, 15th September).

The lamp was c[illegible] by a glass globe, and was provided with a [illegible] white japanned reflector, 36 inches in diameter. A noticeable point in the illumination was the absence of the usual shadows from the mechanism which holds the carbon, whilst the shadows of any objects upon the ground were remarkable for their absence of sharpness of outline.

All the visitors seemed to be very much satisfied with the favourable results obtained with this new lamp, which prognosticated for the system an extensive employment.

There has been a great want of a simple form of electric lamp for lighting up railway stations, churches, or large public halls, which will burn steadily for a long period, and as the Heinrichs' lamp will last for ten to twenty-four hours, without change of carbons, it may prove a dangerous competitor to other systems in use.

Mr. Heinrichs also showed his new electric-motor, which gave most favourable results as a transmitter of power, and which we hope to describe in detail at some future time; at present we will give only a few notes of the results obtained with this motor during the evening.

The current of a Gramme machine driven at 850 revolutions per minute by 1½ to 2 horse-power, was connected by sixty yards of cable to Heinrichs' electric-motor. The revolving armature of this motor weighs over forty pounds, and was driven by the current at a rate of 1,600 revolutions per minute. The motor was then connected by a belt to a grindstone 30 inches in diameter and 4 inches wide; the grindstone was then driven by the motor at a speed of from 230 to 250 revolutions per minute, whilst the motor kept up a speed of 1,100 revolutions per minute. When rough work was put in operation upon the grindstone the speed of the latter was but little reduced. It is stated that the loss of power in this motor, worked by a dynamo-machine at a distance of 60 to 100 yards, was not 20 per cent.

Mr. Heinrichs promises to have in a short time a new single current dynamo-machine for light purposes, and will then be able to give more exact figures as to the illuminating power of his light and how much power is lost by the transmission of power by his new electric-motor, which must be very favourable according to the results obtained.

We are informed by Mr. Heinrichs that the expense of the circular carbons, which were manufactured by Messrs. Johnson and Phillips at their Charlton Works, is not greater than that for straight ones.

The whole system was patented in England and abroad November, 1878.

EDISON's latest electropyre, or electric burner, consists of a small cylinder of pure zircon, heated to whiteness by a surrounding coil of platino-iridium wire.

42

EDISON's call for platinum for his electric lamp has been responded to with interest by Western "prospectors," and a crystalline vein of it has been found in a seam of talc in Santa Clara County, California. The schistose rock in which the talc is imbedded was found to be so hard, however, that the work of quarrying proved unprofitable. Prof. Stewart, nevertheless, thinks that with proper tools it might be made to pay. Drift platinum was once found along with gold in old diggings of Trinity and Humboldt Counties, and the same authority recommends search in that region. Telegraphic Journal Sept 15 187

HEATING METALS IN VACUO BY THE ELECTRIC CURRENT.

Oct 1 1879

A very interesting paper, by Mr. T. A. Edison, was read before the American Association at Saratoga the other day:

"In the course of my experiments on electric lighting," says the author, "I have developed some striking phenomena arising from the heating of metals by flames and by the electric current, especially wires of platinum and platinum alloyed with iridium. These experiments are still in progress.

"The first fact observed was that platinum lost weight when heated in a flame of hydrogen, that the metal coloured the flame green, and that these two results continued until the whole of the platinum in contact with the flame had disappeared.

"A platinum wire, twenty-thousandths of an inch in diameter was wound in the form of a spiral one-eighth of an inch in diameter and half an inch in length. The two ends of the spiral were secured to clamping posts, and the whole apparatus was covered with a glass shade. Upon bringing the spiral to incandescence for twenty minutes that part of the globe in line with the sides of the spiral became slightly darkened; in five hours the deposit became so thick that the incandescent spiral could not be seen through the deposit. This film, which was most perfect, consisted of platinum, and I have no doubt but that large plates of glass might be coated economically by placing them on each side of a large sheet of platinum, kept incandescent by the electric current. This loss in weight, together with the deposit upon the glass, presented a very serious obstacle to the use of metallic wires for giving light by incandescence, but this was easily surmounted after the cause was ascertained. I coated the wire forming the spiral with the oxide of magnesium by dusting upon it finely powdered acetate of magnesium. While incandescent the salt was decomposed by the heat, and there remained a strongly adherent coating of the oxide. This spiral so coated was covered with a glass shade and brought to incandescence for several minutes; but instead of a deposit of platinum upon the glass there was a deposit of the oxide of magnesia. From this and other experiments I became convinced that this effect was due to the washing action of the air upon the spiral; that the loss of weight in and the colouration of the hydrogen flame was also due to the wearing away of the surface of the platina by the attrition produced by the impact of the stream of gases upon the highly incandescent surface, and not to volatilisation, as commonly understood.

"I will now describe other and far more important phenomena observed in my experiments.

"If a short length of platinum wire, one-thousandth of an inch in diameter, be held in the flame of a Bunsen burner, at some part it will fuse and a piece of the wire will be bent at an angle by the action of the globule of melted platinum; in some cases there are several globules formed simultaneously, and the wire assumes a zigzag shape.

"With a wire four-thousandths of an inch in diameter this effect does not take place, as the temperature cannot be raised to equal that of the smaller wire owing to the increased radiating surface and mass. After heating, if the wire be examined under a microscope, that part of the surface which has been incandescent will be found covered with innumerable cracks. If the wire be placed between clamping posts, and heated to incandescence for twenty minutes by the passage of an electric current, the cracks will be so enlarged as to be seen with the naked eye, the wire under the microscope presents a shrunken appearance, and is full of deep cracks. If the current is continued for several hours these effects will so increase that the wire will fall to pieces.

"This disintegration has been noticed in platina long subjected to the action of a flame, by Prof. John W. Draper. The failure of the process of lighting invented by the French chemist, Tessié-du-Motay, who raised sheets of platinum to incandescence by introducing them into a hydrogen flame, was due to the rapid disintegration of the metal. I have ascertained the cause of this phenomenon, and have succeeded in eliminating that which produces it, and in doing so have produced a metal in a state hitherto unknown, and which is absolutely stable at a temperature where nearly all substances melt or are consumed, a metal which, although originally soft and pliable, becomes as homogeneous as glass and as rigid as steel. When wound in the form of a spiral it is as springy and elastic when at the most dazzling incandescence as when cold, and cannot be annealed by any process now commonly known.

"For the cause of this shrinking and cracking of the wire is due entirely to the expansion of the air in the mechanical and physical pores of the platinum, and the contraction upon the escape of the air. Platinum as sold in commerce may be compared to sandstone in which the whole is made of a great number of particles with many air spaces. The sandstone upon melting becomes homogeneous and no air spaces exist. With platinum or any metal the air spaces may be eliminated and the metal made homogeneous by a very simple process. This process I will now describe. I had made a large number of platinum spirals, all of the same size and from the same quality of wire; each spiral presented to the air a radiating surface of three and one-sixteenth of an inch; five of these were brought by the electric current up to the melting point, the light was measured by a photometer, and the average light was equal to four standard candles for each spiral just at the melting point. One of the same kind of spirals was placed in the receiver of an air pump and the air exhausted to two millimetres; a weak current was then passed through the wire to warm it slightly for the purpose of assisting the passage of the air from the pores of the metal into the vacuum. The temperature of the wire was gradually augmented at intervals of ten minutes until it became red. The object of slowly increasing the temperature was to allow the air to pass out gradually and not explosively. Afterward the current was increased at

over

intervals of fifteen minutes. Before each increase in the current the wire was allowed to cool, and the contraction and expansion at these high temperatures caused the wire to weld together at the points previously containing air. In one hour and forty minutes this spiral had reached such a temperature without melting that it was giving a light of twenty-five standard candles, whereas it would undoubtedly have melted before it gave a light of five candles had it not been put through the above process. Several more spirals were afterward tried, with the same result. One spiral which had been brought to these high temperatures more slowly gave a light equal to thirty standard candles. In the open air this spiral gave nearly the same light, although it required more current to keep it at the same temperature.

"Upon examination of these spirals, which had passed through the vacuum process, by the aid of a microscope, no cracks were visible; the wire had become as white as silver, and had a polish which could not be given it by any other means. The wire had a smaller diameter than before treatment, and it was exceedingly difficult to melt in the oxyhydrogen flame, as compared with untreated platinum; it was found that it was as hard as the steel wire used in pianos, and that it could not be annealed at any temperature.

"My experiments with many metals treated by this process have proved to my satisfaction, and I have no hesitation in stating, that what is known as annealing of metals to make them soft and pliable is nothing more than the cracking of the metal. In every case where a hard drawn wire had been annealed a powerful microscope revealed myriads of cracks in the metal.

"Since the experiments of which I have just spoken, I have, by the aid of Sprengel mercury pumps, produced higher exhaustions, and have, by consuming five hours in excluding the air from the wire and intermitting the current a great number of times, succeeded in obtaining a light of eight standard candles from a spiral of wire with a total radiating surface of 1-32 of an inch, or a surface about equal to a grain of buckwheat.

"With spirals of this small size which have not passed through the process the average amount of light given out before melting is less than one standard candle. Thus I am enabled by the increased capacity of platinum to withstand high temperatures, to employ small radiating surfaces, and thus reduce the energy required for candle-light. I can now obtain eight separate jets, each giving out an absolutely steady light, and each equal to sixteen standard candles, or a total of one hundred and twenty-eight candles, by the expenditure of thirty thousand foot pounds of energy, or less than one horse-power.

"As a matter of curiosity I have made spirals of other metals, and excluded the air from them in the manner stated. Common iron wire may be made to give a light greater than platinum not heated. The iron becomes as hard as steel and just as elastic. Nickel is far more refractory than iron. Steel wire used in pianos becomes decarbonised, but remains hard and assumes the colour of silver. Aluminium melts only at a white heat."

EDISON'S ELECTRIC LIGHT.

N.Y. Herald Dec 17 1879

The announcement that on Christmas Eve Mr. Edison would throw open his laboratory to the public and light up Menlo Park with his new electric light seems to have been prematurely made. A HERALD reporter yesterday called on the inventor and asked him concerning the proposed exhibition.

"I never announced that I would show the light on Christmas Eve," was his reply.

"But it has been extensively reported that you would," suggested the reporter.

"I cannot help that," said Mr. Edison. "It was without my authority. I made no promise for Christmas. I had intended to give the exhibition on New Year's and will be all ready to give it on that date if the company that controls the light will permit. Since it has gone out of my hands, you must know," he added, "their wishes in the matter are binding on me. However, I don't think there will be any doubt that the public exhibition will be made on New Year's, but certainly not on Christmas. Ample notice will be given, so that all who desire may come and see it."

"Then, your electric light is all complete?" asked the reporter.

"So far as the work on it is concerned, yes," replied Mr. Edison. "It is finished, but, on account of the latest patents, I am compelled to keep the laboratory closed to all visitors until the public exhibition takes place."

Manufacturer & Builder

PERFORATING GLASS WITH THE ELECTRIC SPARK.—If the glass intended for the perforation is very thick, it is customary to imbed one of the electrodes in a mass of melted resin, placed on the surface of the glass. This operation requires heat, and is tedious, not to speak of the trouble of clearing the glass afterward of the resin, so as to see the perforation.

M. Fages, architect, of Narbonne, France, publishes in the French papers an improved method, which consists in the use of a small, simple apparatus that may serve for any number of experiments. It consists, first, of a rectangular disk of hard rubber 5 by 7 inches, and second, a brass wire, of which the point passes through the rubber and comes flush with the other side, and is held in place by friction or a screw-thread. A plate of this size is necessary for a Ruhmkorff coil, or its equivalent, giving sparks 5 inches long; larger machines require larger plates of rubber.

In order to use this instrument, it is placed horizontally upon a support, with the brass wire below; the latter is then connected with the electric machine, while a few drops of olive oil are placed on top over the place where the brass point reaches through the rubber; the glass plate is then laid on top, taking care not to have any air bubbles between the oil, so that the latter entirely fulfills its purpose, which is to isolate the point. (Any other well isolating oil will do as well). Then the other electrode is placed on top of the glass, and the spark passed. If the glass is slightly displaced sideways, it is easy to perforate it in several places close together.

The only condition necessary to observe in this experiment, is that the plate of hard rubber be large enough and perfectly flat, so as to fit well against the glass plate, making it impossible for the spark to fly off on a sideward path.

SUBDIVISION OF ELECTRIC LIGHT.—It is reported from San Francisco, Cal., that the Molera & Cebrian system of subdividing and distributing electric light is a great success. The method consists in the use of a system of lenses and reflecting mirrors; the first make the rays of light parallel, when the mirrors reflect them and conduct them to any desired distance, without weakening them in intensity, except to a very small degree. On reaching the place to be illuminated, the rays of the parallel beam are made divergent by a distributing lens or reflector. It is claimed that in this way the light of a single electric lamp may be distributed and divided through all the rooms of a hotel without any material loss of intensity. The supply of course is also regulated and controlled by reflectors, so that the light in any of the rooms may be increased or diminished at will.

It is evident that this method dispenses with the use of conducting wires, while it is claimed that the total cost of such a method of illumination is less than that required for gas works. We should not be surprised if this method were found to be more practical and economical than the transportation of the electric current through wires, as the sending of a beam of light

tion of transatlantic steamer, he wants to rest assured that science has done all it can to make his journey safe.

The above remarks were suggested by the opinion expressed recently at the Iron and Steel Institute in Liverpool, that the tests required at present for steel were too stringent and severe. But it was answered that the traveller would not feel as safe as he does were the tests of steel diminished in severity. Criticism was chiefly directed to the tests applied by the Lloyds and the Admiralty to steel used in ship-building only; but it is probable that if stringency is relaxed in one direction, it will be in all. The argument was that although steel makes a better framework for ships than iron, it will not be employed at present, because it must undergo tests proportionately much more severe than those to which iron is subjected—in other words, the

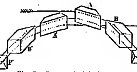

Fig. 2.—Course of Light in Prisms.

manufacturers, or some of them, contend that under much lighter tests than those now required steel framework would be quite as strong as the iron framework which the authorities constantly approve. But this may be an argument against the sufficiency of the iron tests rather than against the stringency of the steel tests.

Whether it is or not, however, Dr. Siemens, than whom no man ought to be more competent to speak on the subject, pointed out a difference between iron and steel which appears to justify the maintenance of the severest tests. Iron, he said, always holds together, except when fractured by a blow under peculiar circumstances; its tendency is to hold together when struck or strained, whether it is of good or poor quality. But this is not the case with all steel. The best steel, it is true, will bend like leather rather than break; but anything inferior to that quality is far more liable to disastrous fracture than iron. Hence, said Dr. Siemens, do not diminish the tests of steel, but rather increase their severity.

Practically, this positive expression of opinion from so high an authority settles the question for the time being. We do not mean that there was no dissension from the views of Dr. Siemens, but none of the steel tests under consideration are likely to be relaxed in opposition to his emphatic advice. As the maintenance of a high standard of excellence in Great Britain is conducive to the maintenance of a like standard in this country, we regard this result with content.

EDISON'S NEW LIGHT.

The little village of Menlo Park, New Jersey, is just now the centre of attraction for scientific men and all those interested in human progress. In it Mr. Thomas A. Edison, one of the youngest and greatest inventors of the age, is toiling sedulously day and night with an able corps of assistants to perfect a new method of artificial illumination that now bids fair to cast a shadow upon all illuminating devices heretofore known. The eyes of the civilized world are upon him, and the daily achievements of his busy brain, as they are heralded throughout the length and breadth of the earth, along the ocean's bottom, and through the air above, by the same mysterious force and substance which forms the basis of all his experiments, are causing tremors of excitement and wonder in all the arteries of commerce. Until now, men of science and great practical experience have declared that the obstacles which Mr. Edison has now overcome were insurmountable; but he holds up his little "carbon loop," and they subside. For forty years inventors and savans have been struggling with this identical problem, and with this same well known principle in view; but success continually eluded their grasp, and they said it was impossible. Mr. Edison now steps to the front with his little "vacuum" almost perfect. The learned gentlemen are skeptical, but they watch his continuously burning lights in breathless anxiety. Mr. Sawyer, a man who has devoted much of his life to the solution of this same problem, sees defects; but the beautiful lights burn on, and Mr. Edison is surprised at the manner and success of his own achievements.

The electric light is not, as many have supposed, a new invention by any means. In fact the main idea now employed in the Edison lamp was used thirty-five years ago, and even in that early stage of its development it created consternation among gas men. Carbons were used in a vacuum, as now, and the light was clear and bright. But owing to many imperfections, not well understood then, these carbons burned up rapidly, and the lamps were practically a failure. Since that time various parties in this and foreign lands have been studying and experimenting to remedy these existing defects, and now for a year past various forms of electric lamps have been in operation in New York, and in other large cities and manufactories throughout the world. Among these experimenters none have labored so diligently and with such untiring zeal as Mr. Edison, especially in late years. Dejected and well nigh broken down in mind and body at times when nothing but failure seemed to impregnate the very atmosphere of his well-appointed laboratory, he toiled on day and night. Ubiquitous reporters sought him out and stuck their enterprising pencils into his half-matured plans. And seventeen months ago, the newspapers proclaimed the startling news that Edison had solved the whole problem of electric lighting with his platinum lamp. But Mr. Edison himself knew better and pursued his experiments with redoubled energy. He found he was on the wrong track and uncouraging reassertions of the absolute impossibility of success poured in upon him anew from all sides.

While seated one day before a mass of lamp-black and tar, used in his laboratory for the manufacture of his telephones, he rolled some of the material between his fingers and found it could be drawn out into a thread. The idea flashed into his mind of making a carbon thread for his electric lamp burner. And from this simple suggestion has proceeded the carbon resistant lamps that illuminate Menlo Park to-day. One of the most skilled glass-blowers of Europe was summoned to his aid; and with his assistance, together with a complex air-pump which Edison had modified to suit his purpose, he finally succeeded in producing the most perfect vacuum ever obtained, and sealing it with only a millionth part of the original volume of air left therein, which is so rarefied that when an electric current is passed through it to the carbon loop, the radiant light toward which a world is now looking with anxious eyes is produced. He found his lamp-black carbons still imperfect, however, succeeded better with common sewing thread; and finally paper, which proved the very substance wanted, and which is the material forming the burner of every one of those fifty lamps burning in Menlo Park to-day. A slender thread of bristol-board paper, clamped out in the form of a ring about an inch in diameter, and carbonized, is held in a small platinum holder, and tightly sealed in the glass globe or vacuum mentioned above. This is connected with a powerful electric generator, and is the latest form of Mr. Edison's lamp. The entire lamp is four inches long, can readily be removed from fixture, and will cost about twenty-five cents to make. The entire cost of the light cannot yet be definitely stated, but it is claimed to be cheaper than gas, and very much better. The flame being tightly enclosed and neither match nor taper of any kind required to light it, much danger from fires will be averted by the use of this light. Whatever further time and testimony may show Mr. Edison has certainly produced an incandescent electric lamp which will work, and does work; and this no man has ever done before him. Having succeeded, therefore, the lamp and light are strictly his, and still the young inventor keeps at work. All honor to the great scientist.

48

have a 20-seconds period, and the invisibility only 15 seconds. The Start and the St. Agnes would then give a flash every 10 seconds, and the Wolf a flash every five seconds, which is the same as Buchan Ness, the Rhynns of Islay, and the little Ross, on the Scottish coast, undoubtedly the three best revolving lights in the world. What an unspeakable improvement this would be to the lighting of the English Channel! The triple-flash light of the Royal Sovereign Shoals Lightship is at present very admirable, and to a patient enough observer, with time enough to spare, it is thoroughly distinctive. But the 37 seconds of darkness is a serious defect of that light, and the slowness of the three flashes, occupying the remaining 23 seconds of the period, is an altogether unnecessary derogation from the distinctiveness of character which greater speed would give them. Three short flashes in three or four seconds, with an interval of six seconds of darkness, would have an instantly recognisable rhythm (letter S of the Morse flashing alphabet); and, when once described, the light would be known to be what it is and nothing else, even before the completion of two of its 10-seconds periods.

"Revolving lights are, however, but a small minority of all the lighthouses of the world. Of the 623 lights of the British and Irish coasts, just 110 are revolving lights, and the remaining 513 are fixed, and there is a crying want of distinction for fixed lights. The distinction by colour alone ought to be prohibited for all lighthouse lights, on account of its liability to confusion with ships' and steamers' side-lights. Southsea Castle, with its red and green port and starboard side-lights, seems as if actually planned to lure on to destruction an unsuspecting enemy carefully approaching the coast with Thomas Gray's happy rule well impressed on his mind:

"'Green to green, and red to red,
Perfect safety, go ahead.'

He does so, and is wrecked on Southsea beach.

"My proposal for supplying the want is to distinguish every fixed light by a rapid group of two or three dot-dash eclipses, the shorter, or dot, of about half a second duration, and the dash three times as long as the dot, with intervals of light of about half a second between the eclipses of the group, and of five or six seconds between the groups, so that in no case should the period be more than ten or twelve seconds. This proposal has been carried into effect with perfect success in Holywood Bank Light, Belfast Lough, now the leading light for ships entering the Lough, but which until 1874 was enclosed in a red glass lantern and was only visible five miles, and was constantly liable to be mistaken for a sailing vessel's port-side light entering or leaving the harbour of Belfast, or the crowded anchorage of Whitehouse Roads. In 1874 the red glass was removed, and the light was marked by dot, dot, dash (— — ——, or letter U), repeated every ten or twelve seconds, and has been so ever since. It is now recognised with absolute certainty practically as soon as seen in ordinary weather from the mouth of the Lough, ten miles off, and has proved most serviceable as leading light for ships bound for Belfast or entering the Lough.

"It is much to be desired that the dot-dash system should be seriously considered by the lighthouse authorities of our islands. Hitherto, when attention has been called to it, it has been dismissed with a pleasantry, 'Winking lights won't do,' or else something utterly different has been gravely considered and justly condemned. It is satisfactory now to know that the Deputy Master of the Trinity Board, Sir Richard Collinson, K.C.B., has, after its character was correctly put before him by the recent Select Committee of the House of Commons on Electric Lighting, given it his approval in the concluding answers of his evidence.

"Is it too much to hope that when the new Eddystone Lighthouse is finished the light shall not be, as hitherto, an undistinguished fixed light, but a fixed light distinguished by a group of dot-dash eclipses — such as dot, dash, dot (— ——— — letter R)—which is particularly easily distinguished by its rhythmical character; and that the Needles Light, which shows red over a great area of sea south of it, and when undistinguished, as at present, is liable to be inconveniently and even dangerously mistaken for a ship's port-side light, shall have a distinctive dash, dot (——— — or letter N) given to it, which, whether in its red or on its white sectors, will instantly show it to be itself and no other light at sea or on shore? The five years' practical demonstration of the dot-dash system in Belfast Lough ought surely to weigh with the authorities. The introduction of a well-proved remedy for an admitted defect of our lighthouse system should not need that advocacy which moved the unjust judge, and the seafaring world should not suffer the delay in gaining a great benefit which the strict following of that judge's precedent would entail.

"I remain, your obedient servant,
"WILLIAM THOMSON.
"The University, Glasgow."

HOWELL'S BATTERIES.*

Telegraphic Journal Dec. 15/79

By C. F. HOCKIN.

Having lately tested several of these elements, I think the results may be interesting to some of your readers, particularly as the cell in question is, I believe, a very good one, and has a higher electromotive force than any cell with which I am acquainted.

The plates are zinc and carbon.

A cylindrical glazed porcelain vessel, about 6½ inches high and 5½ inches in diameter, contains a smaller cylinder 6¼ inches high and 2½ inches in diameter, of the same material, which is open at both ends and has four longitudinal slots in its walls.

The smaller cylinder stands with its axis vertical in the larger vessel.

In the space between the inner wall of the larger cylinder and the small cylinder (called the separator) is placed first a rod of carbon, on to which is fitted a terminal.

Around this block is a mass of broken carbon and peroxide of manganese, filling the clear space described to within about 1½ inches of the top of the cylinder. On the top of the mass is placed a layer of white manganese or native sulphate of

* An illustrated description of this battery was given in our last number.—Ed. Tel. Journ.

D shaped permanent magnet, one pole being made longer than the other and placed uppermost. Below this long pole is fixed a single bobbin electro-magnet having a soft iron core passing through the long pole of the permanent magnet, and magnetised by it, and made in two parts, the lower part being fixed in the bobbin and the upper part capable of being adjusted at any required distance from the other by a screw, shown at the top of the bobbin, carried on a bracket on the long pole of the magnet.

Below the shorter pole of the permanent magnet and also directly below the top electro-magnet is placed another single bobbin electro-magnet, with an iron core capable of being adjusted in regard to its height above the coil by an adjusting screw below. It will thus be seen that the iron cores of the electro-magnets face each other, with a space

AN IMPROVEMENT IN ELECTRIC LAMPS.

[BY TELEGRAPH TO THE TRIBUNE.]

CINCINNATI, Nov. 5.—A very clever mechanism is being perfected by two young electricians of this city, W. M. Thomas and L. W. Skinner, to avoid the constant flickering in all electric lamps now in use. The arrangement is entirely automatic, the current itself regulating the distance between the upper and lower carbons. The lower carbon is connected through the frame of the lamp with an insulated wire at the top to the positive pole of the battery. The upper carbon is taken through a coil of insulated wire connected at the top with the negative pole of the battery. On top of the carbon and fastened to it is a piece of soft iron of the same shape, also fitting into the coil. The iron and carbon are nearly balanced by two weights attached to two wheels which run up and down on each side of the coil. When these wheels touch the coil the insulation is taken off and the wheels touching the wire lead off the current from the lower part of the coil and by another wire to the upper carbon. The current only passing through the upper part of the coil attracts the soft iron upward. When the carbon burns slowly away the current is reduced and has less lifting force. The carbon slowly sinks. The wheel and weight also sink. When the carbon again burns away the strength of the current is reduced and the carbon gradually drops. The weights are small metal buckets to be filled with shot according to the strength of the battery. The advantage of the light is not only its steadiness, but the sensitive regulation of the length of the arc, which gives a good soft color to the light and does away with the necessity of ground glass globes. Three patents have already been applied for and allowed, the claim being that by this means the current works automatically. Clutches, glycerine cups, or clockwork are all done away with in this way.

the permanent magnet, as it is magnetised by the line current only when passing.

No reacting spring to raise the vibrating armature is needed, as the permanent magnet magnetising the pole or core of the upper electro-magnet raises the armature directly the line current is off, and this degree of magnetism is regulated as described by having the upper core in two parts adjustable to each other.

If the apparatus is worked on the "double" current system then it can be much more delicately adjusted, as the reversal can be caused to raise the armature to its normal position.

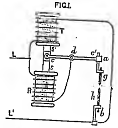
The instrument when adjusted will give a good readable sound when traversed by a current of about 10 milliwebers (1 Daniell cell through 100 ohms resistance).

A small galvanometer is placed in the front of the instrument to indicate whether a current is passing or not, should the instrument fail to work.

SIEMENS' DIFFERENTIAL ELECTRIC LAMP.

The general principle of this lamp is shown by fig. 1: g and h indicate the carbons held respectively in the sockets a and b, and provided with means of feeding as they are consumed. The one

FIG. 1.



socket a is attached to one arm c^1 of a lever pivoted at d, and having its opposite arm c connected to a piece of non-magnetic material uniting a pair of iron cores s, s^1. The core s is free to play up and down within a solenoid R, the coil of which is of large wire offering small resistance, and forms part of the lamp circuit. The core s^1 is free to play up and down within a solenoid T having a coil of smaller wire offering greater resistance than the coil of R. The coil of T is in a circuit external to the lamp, that is to say, joining the conductors L, L', excluding the carbons. When the solenoid R, being excited, draws in its core s, the points of the carbons are separated; when on the other hand the solenoid T draws in its core s^1 the carbons are caused to approach each other. As the relative force of the two solenoids depends upon the strengths of the currents of electricity passing respectively through their coils, and as this depends upon the relative resistance of their respective circuits, the one circuit

A RIVAL OF THE ELECTRICAL LIGHT.

An intensified gaslight, by [illegible] called the "albo carbon light," is attracting considerable attention in England at present. Its special advantages are that it economizes the consumption and improves the quality of the gas, and involves no change in mains, meters or piping, or the general apparatus of gas service. It is also claimed by the patentees that albo-carbon causes no obstruction and leaves no residuum; and that the evaporation of the substance under heat is so thorough that vessels in which it is used may be replenished without any fear of accumulating deposits. A variety of interesting photometric tests were recently applied to this light at an exhibition in London; and one of the most pleasing effects produced was that of its hue, which was cheerful and sunny as well as intensely brilliant; and the shadows cast by objects within its range were of a subdued tone quite different from the intense darkness that contrasts so unpleasingly with the moonlight brightness of the electric light, which requires at present for its production elaborate machinery not needed in connection with albo-carbon.

This substance, used as an adjunct to gaslight, imparts to the latter a warm, sustained, and steady light, that does not in spite of its strength, fatigue or discommode the eye. As employed as an auxiliary to common gas, the improved light consists of some properties of pure white carbon in the solid form of small cylinders, having much the appearance of sticks of pure white candy. The apparatus required to adapt the feeder and enricher to an ordinary gas-burner is so simple that it demands a management no more skillful than that needed to fill and trim a common table lamp.

ELECTRIC LIGHT.

Latest Developments in the Science of Illumination.

What Edison Has Been Engaged in Perfecting at Menlo Park.

Illustrations of the Machinery Producing the Light.

The Inventor's Claims as to What It Will Accomplish.

What the Gas Men Have to Say on the Subject.

They Regard the System as Entirely Too Expensive,

And Claim to Prove This Upon Edison's Own Statements.

Why Electricity May Not Supersede Coal Gas.

Mr. Edison has long been busily engaged almost day and night, with a trained corps of able assistants, and with a large factory and laboratory at his service, more than a year, in the task of inventing a practical electric light to supersede gas in houses and rooms, as well as in streets and public halls. Within this time he has invented a number of new and ingenious electric machines and devices—notably a new and more economical electric generator than has ever before been known, which is part of his electric light machinery, several electric motors, a number of forms of lamps, etc., besides several inventions and improvements not pertaining to this subject. He has also made some surprising scientific discoveries, one of the most notable of which is the condensation of platinum and other metals by repeated heating in a vacuum. He has invented new processes for obtaining various chemicals; he has overcome the difficulties of subdividing an electric current, and of regulating its subdivisions and intensity by a simple arrangement at the generator. In all, he has, during this time, made at least fifty or sixty inventions which may prove of great future value. But the attention of the world has been most strongly fixed upon his attempts to create a perfect, or nearly perfect, electric light for ordinary use. He now thinks he has succeeded; and he is daily giving exhibitions to crowds of visitors of his lamp and its accompanying machinery.

Certainly this lamp and machinery are exceedingly, we may fairly say are marvellously simple. The lamp itself can be manufactured and sold at a cost of twenty-five cents. It contains a loop of charred paper of the kind known as fine bristol board, about as large as a bit of coarse black thread, say two inches long, bent in the form of a horseshoe. These horseshoes are first cut by dies from sheets of bristol board. They are, when cut, the size of a thick and coarse woolen yarn. They are then laid so as not to overlap each other in an iron box with a tight cover. Then a sheet of tissue paper is put over them; and then another layer of horseshoes, and so on. On top of all is a weight of a pure carbon block. The box is then shut, and heated red or white hot in a furnace, till the paper is thoroughly charred, so that it comes out as black [illegible] handle, the horseshoes are carefully taken out, and each perfect one is fixed in minute clamps to the ends of two small platinum wires, set in the base of a lamp. The paper is now frail, and has to be handled delicately, but after electricity has flowed through it awhile, it becomes so tough that there is no danger of injuring it by any jar, or any handling which the glass of the lamp will stand without breaking. These loops of charred paper, when the electric current flows through them, glow with a mellow and bright light, which neither flickers nor sparkles, but is as steady as sunlight. Each horseshoe is covered by a pear-shaped glass globe, about two inches wide and four inches high. The air is exhausted from this globe by a machine invented by Mr. Edison, and more thoroughly exhausted than has ever before been considered possible. The horseshoes are thus left in a practically perfect vacuum. The platinum wires which go through the bottom of the glass are welded directly to the glass. The glass is of such quality that it expands the same as the wires. Besides, the wires pass first through one thickness of glass, to which they are welded, then, through a vacuum chamber as large as a ch[illegible], and then through another floor of glass to which they are again welded. In order for air to get in and around the wires it would have to pass through the first thickness of glass, then through the vacuum chamber, and then through another floor of glass. We now present a cut of the lamp, which is so simple as to be easily understood.

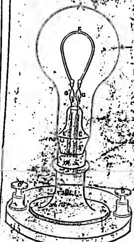


FIG. 1.—EDISON'S COMPLETE ELECTRIC LAMP.

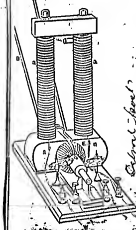
In this figure F is the charred paper horseshoe: A is the glass globe; B is the standard, of wood or metal; D D are the screws for attaching the electric wires; E E are the vacuum chamber, with the wires passing through it; G G are platinum clamps with their fine platinum wires. The current of electricity being turned on, by connecting this lamp with the wires from a generator, the horseshoe carbon immediately glows with light. By simply turning either of the screws the light ceases, or can be turned down to any desired dimness, or can be turned on again. The light goes just as well under water, upside down, laid on its side, hung up anywhere, or laid down in any position. The cut represents a table lamp. So long as the glass globe remains unbroken, it is all right; but the moment air gets into the globe, the light ceases. It can be carried anywhere in the hand, like a lamp, so long as the two wires are kept fastened to it. Jarring does not affect its steadiness. The glass does not get hot enough to burn your hands. It is, in fact, so perfectly steady, without flicker, or sparkle, or flame, as to be restful to the eyes. Its intensity is regulated at the generator, and never varies. It can be made so bright that the eye cannot look at it; but it really is of just the brightness the customer asks for; and it is kept at just that brightness without change so long as he desires. It will be furnished singly, or in chandelier clusters, with any base, or no base, or in any form, for any position desired. It can be arranged so that each light in a house may be started by itself, when wanted, and all be started at once if desired, so that a person in bed in the night, by simply touching a thumbscrew placed within reach of his hand, can instantly light every room in the house.

We now come to the generator, by means of which the power of the steam engine is converted into electricity, and the current of electricity is regulated. This machine Edison has named in honor of Faraday.



Detroit "Free Press" Sunday Jan 4th 1880

FIG. 2.—THE FARADAY MACHINE.

The reader must be supposed to have some knowledge of electric generating machines in order to understand this machine. A A are two upright iron columns, three feet high and three inches in diameter, wound with coarse wire, and resting upon the base N and S, which form its magnetic poles. This part of the apparatus is called the field of force magnet. Fixed on an angle so as to freely revolve between the poles N and S is a cylindrical armature of wood (E), wound parallel to its axis with fine iron wire. When this cylinder or armature is made to revolve rapidly between the magnetic poles N and S, by means of the belt B, driven by an engine (not shown in the cut), there is generated in the wire surrounding the armature (E) strong currents of electricity, which are carried off by the wires W W to the electric lamps.

By constructing this machine in a slightly different form it becomes a motor for running a sewing machine or doing other mechanical work when a current is driven through it from the above machine. One of these motors can be run with the same current which will run a lamp, so that the current can be used to run a sewing machine by day and a lamp by night.

The current is regulated at the generator by turning a small wheel. There is also a remarkably ingenious register to show the amount used by each consumer, just as a gas meter registers the amount of gas burned; but we cannot illustrate these devices, which would be understood only by those having some knowledge of electric science and art.

It must not be taken for granted that Mr. Edison regards this lamp as really perfect. He is still experimenting. He thinks he has hit upon the right system, but he is trying all sorts of forms in place of the horseshoe, all sorts of shaped glasses and different kinds of paper, and he is continually meditating improvements. In fact he can't help, with his inventive genius, constantly thinking of new experiments. His inventive mind never was and never can be entirely satisfied with anything. But he pronounces this light a great success.

What the Gas Men Say.

In connection with the above, it will be interesting to know what the men most interested in the manufacture of gas have to say on the subject of this new alleged rival, how badly they are scared, and what they expect to do about it. One of the most prominent and well-known representatives of the gas manufacturing interests in the city is

MR. WILLIAM H. FITCH,

of the Mutual gas company. He talked freely on the subject, and his views are given in full.

"There is a great deal of science in these newspapers, nowadays," Mr. Fitch remarked. "Now, here's two pages with illustrations," picking up a copy of the New York Herald. "Now I am not going to tell you what I think. I will let you figure for yourself. You need not say Fitch said so, once. Here's something about it in the Herald, Edison's own statement: 'Although the plans have not been fully consummated for general illumination, an outline of the probable system to be adopted is the locating of central stations in large cities in such a manner that each station will supply an area of about one-third of a mile. In each station there will be one or two engines of immense power, which will drive several generating machines, each generating machine supplying about 50 lamps.'

"Now you just figure that out for yourself. There are 18 square miles of this city lighted with gas. You see it makes 51 stations necessary. He says it will require two engines at each station; and why? If there is only one the minute the engine stops the section supplied by it is in the dark. So two engines are necessary. But you may calculate on one. I won't calculate it; I want you to;" and the veteran of his calling pushed a pad of paper toward his interrogator. "Just see for yourself. I don't misstate it nor misquote Mr. Edison. Here he says 'engines of immense power.' That you would regard as meaning about the largest made; such as they have up at the water works, for instance. Now these cost $125,000 apiece. Take half the number of engines that he says are required, only one for each station. The engines alone, without real estate, without buildings, without boilers, generating machines, or anything else, will cost $6,375,000. That is a beginning. But all these other things have to be bought. If he needs duplicate engines he needs duplicate batteries of boilers. He must have buildings and generators, and all that, for 51 'plants.' Well, all these will cost at least $15,000,000. But give these little things to him. Concede these trifles for the sake of the argument. At the lowest estimate it will require four men at each station. That is a very small number. That makes 216 men for the generation of the light alone; more than three times as many men as both gas companies employ. I don't see any economy or saving sticking out there.

"In the last place. The fuel required to run all these engines would be twice as much as is now required by both companies for gas making material. The entire amount of money paid by this city for gas to both companies, from public and private parties, suppose it were all clear profit, would not pay 3 per cent. interest on the cost of making Mr. Edison's light, supposing it to be a success in all particulars, just as he claims.

"The only paper outside of this city which I have seen that is sensible on the subject is the St. Louis Globe-Democrat. They have an article in which they speak of Mr. Edison as a fraud; that he deserves to be called so. From the very first, when he has said he has discovered anything, he at once throws out remarks as to the effect it will have on gas stocks. If he was a true scientist, and working for science, he would say nothing about gas stocks.

"You can take these facts, and figure it out for yourself. You needn't figure it out for me at all. Because, although it is true, it would simply invalidate it to a good many people to let them know that Fitch said it, on account of my being connected with the gas company."

"How do you account for the recent fall in gas stocks?"

"That is another thing I will tell you about and you may figure it out. The people I know say the gas stocks are going to blank, and all that. But you see it is in this way. In New York there is a good deal of competition and they are not paying dividends regularly every year. So gas stocks would have declined without Edison. You have noticed that gas stocks in Montreal are lower a dollar or two a share. So they are all over the country, for this simple reason: Fuel will be $2 or $2 50 per ton higher next spring than we have paid for several years, and it is likely to remain so for 5 or 10 years to come. There will be just that much less money made by the companies. You can't reduce the price of gas. That is a difficult thing to do. We have to make $2 or $3 on a ton less, and that is a good deal. This amounts to a good deal more than is indicated by the depreciation of stocks. Gas stocks in England have gone down for very similar reasons. The price of fuel and of labor and everything have gone up. Gas is about the only thing which has not been increased in price; so the dividends paid are necessarily less and must be for years to come. This has been brought about within the last six months and would have happened any way, for this boom in coal has taken place within six months. It has not affected our present contract, because that was made in June. Since the contracts were made coal has gone up from $2 50 to $3 in price per ton. The cost of transportation has more than doubled. I made a fortunate contract, and the company that sells our coal had to pay twice as much for transportation as they had expected, and on the first of November would have gladly paid me $2 a ton not to take the coal."

"You apparently do not feel very much frightened about this new invention."

"Among intelligent people—that is, intelligent on this subject—all these things are taken into account. No doubt there are very many intelligent people on other subjects who would and do get excited about it, and think nothing about the cost of it. I presume some college presidents and others equally well informed might. I notice that some one asked Mr. Edison the other day, at Menlo Park, what it was going to cost him to accomplish this. He said they could furnish the equivalent of eight gas jets like that one up there, per horse power of their engines. Now if you want to compute how many horse power it would take to light your office, and then see how many tons of coal per day it would take, and then compare it with your gas bill, although I have no doubt it is large, you would find the electric light would cost the most, after all the apparatus was paid for. And the same is true of any other building in the city. Here is the whole thing in a nutshell: The fuel that runs the electric generator will make more light in gas than Edison can make with his electric light. It has al-

57

52

ways been so, and always will I think, till he can gather electricity out of the atmosphere by an inexpensive method. At present he can't touch gas in any way, shape or manner, if it sells for less than $10 per thousand feet. This I say is true, figuring only from the data he himself furnishes.

"Of course there are people who will take this thing up at once. The wish is father to the thought. People would like to see it done. So would I. If the world can get a cheaper light than gas I will get it, and light the city of Detroit with it. I calculate to stay in the business. I had as soon light the city with electricity as with gas. Whenever I find anything that can be furnished cheaper than gas I am going to get it for the good people of Detroit. I don't propose that anybody else shall get it for them either.

"Of course there would have to be just as many book-keepers and men outside the works as now. The labor in this office, the clerical work, depends on the number of people, not the nature of the article furnished. The thing which is attracting so much attention is the cheapness of the burner, which, he says, he can furnish for 25 cents. That's a mere bagatelle in the cost of the light, and practically does not enter into the consideration at all."

As the reporter withdrew Mr. Flich remarked, "You see, young man, we are not much afraid of the Edison electric light yet."

ALEXANDER LEWIS,

president of the Detroit gas light company said: "The invention has not yet proved itself practicable to any extent. If it should be, I think the cost would stand against it at all times. We know of nothing yet that will take the place of coal gas, from the fact that it can be manufactured much cheaper than Mr. Edison can run his lamps. I presume it would take at least 50 engines to supply this city. The number of men required to run them would be much greater than at present are necessary. So I don't think the gas people need to dispose of their stock on account of the electric light. Of course the expense of the burner is trifling. The expense of making the cost of running the whole thing is what makes the difficulty."

"As between the two, petroleum and electricity, which do you consider the greater enemy to the gas men?"

"I don't think the gas men have either to fear. The convenience and safety of gas make it the most desirable light we have. Of course the electric light would be just as safe as gas; but I do not think it can be brought into such general use as gas. Scientific men have investigated this thing out, and they say it cannot compete with gas. We do not regard the occupation of the gas men as gone, by any means. Gas companies are not making more than a fair profit, and have not [illegible] years. Gas is furnished as cheap as it can [illegible] reasonably, and there would [illegible] to be no [illegible] prospect of its being superseded."

JEROME CROUL,

one of the directors of the Detroit gas company, said: "Mr. Edison and his friends seem very sanguine that they have attained success. If it is such a great benefit to the public, of course we shall have to accept the inevitable. I have had no practical demonstration of it and know nothing of the details of it. It will have to be thoroughly demonstrated before the public will accept of it. At present I regard it as an experiment.

"Gas, like water, does not cost much; it is the getting it to the customers that costs. Water does not cost anything; but the pipes and works do. We have a three million dollar plant here. It is the same way with light. And Mr. Edison proposes to send light in the same way, through pipes. The wires, I understand, are to be enclosed in gutta percha, and then in pipes. I can demonstrate the workings of this thing, as it is represented to me by Mr. McKenzie, Mr. Edison's agent here. They claim to be able to supply the light from any given station for a radius of 3,000 feet. In order to supply the whole city, numerous stations must be established, and when you get 20 or 30 of them, with all the necessary outlay for engines, machinery, fuel and labor, it seems as though the expense must be greater than it is at present.

JACOB S. FARRAND,

another of the directors of the company, said the whole matter hinged on two questions: the practicability and the cost. "Of course," he said, "we do not feel at all sure Mr. Edison has accomplished what he proposes. If the light is better than gas people will buy it. We have all along regarded petroleum as the greatest injury to our business that we have. We see no reason to change our opinion."

G. V. N. LOTHROP

being questioned on the subject, smiled affably and remarked, "I am in my usual good health, sir, and at your service; but I have no opinion to express on the subject of the electric light."

The Cost of the Electric Light.—The following particulars of the cost of producing the electric light for factory illumination will be read, says *Engineer*, with considerable interest. The plant consists of one 8-horse power Marshall's engine fitted with automatic expansion gear, two Gramme dynamo machines, two lamps, and one spare lamp. This plant was established one year ago at the pipe foundry of the Stanton Iron Works Company, Limited, near Nottingham, and the following figures show the result of twelve months' working:

	£	s.	d.
Interest and depreciation on £361 10s., first cost at 10 per cent.	36	10	0
Wages of crane tenters attending lamps	15	0	0
Oil waste, repairs to engine, &c. ..	3	12	3
Repairs to machines, cables, &c. ..	1	2	0
" lamps	8	2	6
657½ meters of carbons, at 2s. 2d. per meter	71	1	3
	135	11	5

The hours booked against the foundry were 3,621 in 302 working days, but the lamps were probably at 4,000 hours; taking the smaller figure the cost is: for the year commencing Oct. 26, 1878 .. .. .. } 4s. 6d. per shop per hour of the year ending Oct. 26, 1879 } 4,000 candles.

ELECTRIC LIGHT PHOTOGRAPHY.

THE GRAPHIC was the first in this country to use artificial light in photography at night, and it has no difficulty in perfecting [illegible] results by its processes. Mr. Clements, formerly in the service of THE GRAPHIC, and now of the firm of Willis & Clements, of No. 17 East Seventeenth street, is not inclined to attach much importance to Mr. Dunn's recent exhibition of electric photography, as he believes that after the novelty wears off there will be little or no demand for photographs by this process after nightfall. "A few years ago," he said, "to secure a negative by the old process we had to wait for favorable weather, but such important improvements have been made in the art that now it requires but a few seconds, and almost any kind of weather will answer. The electric light is a valuable auxiliary in photography—particularly in our system which is known as the platinotype. By it we enlarge to life size from photographs of every description, depending altogether with the solar camera." The photographic process of Messrs. Willis & Clements is simple and interesting. Their electric light is produced by a Weston Dynamo machine of four-horse power, located in the front office, and connecting [illegible] wire with the lantern and camera in a small room in the rear. In this lantern is a condensing lens, in front of which is placed the negative. The light passes through it to the focusing lens, throwing the image on to the disc or screen on which is placed prepared or sensitive paper. Afterwards it is subjected to their process, developing into wonderfully clear and handsome platinotypes.

Mr. Clements said that the system of securing photographs by the electric light was first utilized by a French scientist several years ago, whose system, however, was improved upon by Mr. Vandercyde, an American, who gave exhibitions in London a year and a half ago. Mr. Dunn will not obtain portraits at all comparable with those made during the day unless he diffuses the light so as to give transparency to the shadows; he must also shut off the direct light from the subject, for the glare is more than the average customer can stand.

THE ELECTRIC LIGHT.

MR. EDITOR:—The question is, is the electric light a success? Now I can, as a scientist, satisfy any of your readers right here, that this thing is certainly one thing or the other—a success or not a success. From the roaring accounts given by parties who went to Menlo Park and came back loaded down and boiling over at the brim, I was induced on New Year night to go down to the Electric Depot and make a thorough investigation to satisfy myself as to the marvellous stories told in town, in regard to this tremendous thing. Some of the most enthusiastic advised me to go and investigate, by all means, and never mind the cost, if my finances were shrunk, hypothecate my house, horse, watch or any thing. Well, I hypothecated my jack-knife, realized twenty-five cents, bought a ticket, sat all afternoon in the depot so as to get a good seat in the 7:20 train, p. m., when we sailed from the depot. I found 160 more blind adventurers looking for light. Before we arrived at our destination I was in full possession of all the points of any interest. One individual informed me that a friend of his, who was chuck full of the electric light, informed him that a $100 share was worth $7,000 today; would be worth $10,000 in two years and $100,000 in ten years, he said he knew that his friend was posted and was in earnest, for when he uttered the $100,000 he slammed his fist so hard on the counter that the adjoining storekeeper ran out in the street thinking there was an explosion or earthquake near by. I also learned that the Rothschilds had offered $5,000,000 for all Europe, Africa and the state of Maine. Also that Rahway was going to be lit up in two weeks by two lamps placed at the depot, these running in combination with the light God had given us, would give us perpetual daylight from now until doomsday. When we got to Menlo Park there was none of that artificial daylight so much talked about, and we couldn't see to pick up a pin a dark street, any better by the electric light there, than we could by our gas house lightning-bugs here. Like Grant, we saw a great many people, and among them some very fine people, who satisfied us on one point, and that is, if the electric light could not be divided, the electric globes could be, because several of the globes were deposited in the several pockets of three several different persons on that very evening and we are satisfied they were so well divided that they will never get together again. In our ramble through the building we heard several very sensible questions asked that were not answered, such as—"Does Mr. Edison think this is a success?" "Can one of the little globes be attached to a wire clothes-line in the yard and give light?" "Wouldn't these little things bring thunder and lightening in the house?" One sarcastic looking individual said that the altar would not be anything new, as there was plenty of that in some houses now. We would like to have had the pluck to ask if loafers could stop off the lights by laying bars of iron on the wires as effectually as Mr. Edison could, by his regular process. Now, in conclusion, I will say this; if Mr. Edison is not fooling us all the time with gas, instead of electricity, it is all right. Mind, he has gas in there all the time, and some of New York's scientific men may find out something yet. There is one thing certain and that is, there is such a place as Menlo Park and there is a queer kind of light looming up there.

Telegraphic Journal Oct 15 1879

THE ELECTRIC LIGHT ON WATERLOO BRIDGE.

A FURTHER step in the development of the electric light in the metropolis has been effected by the extension of the Jablochkoff system, which has for some time past illuminated the Victoria Embankment, to the lighting of Waterloo Bridge. For this purpose ten lamps had been fitted up with the Jablochkoff electric candle, nine of these being situated on the bridge, and one on the refuge at the Strand end in the middle of the roadway.

In addition there were five Jablochkoff candles fixed in the machinery shed under the Charing-cross railway bridge, thus adding fifteen lights to the forty previously maintained. Fifty-five lights are now sustained by an engine of 20 horse-power nominal, although there were many persons who doubted whether so many as twenty lights could be kept going. Commencing some months ago with twenty, the number of lights was subsequently increased to forty, now to fifty-five, to be soon enlarged to si[illegible]. Three pairs of machines are now at work, each [illegible] dated to sustain twenty lights. Preparations are [illegible] made to place four lights in the Board-room of the [illegible]tropolitan Board at Spring-gardens, and a fifth [illegible] the principal entrance to the building.

The [illegible] produced by the lighting up of the bridge is ext[illegible] good, and at the Strand end very striking, the ill[illegible]ation of Somerset House being singularly pictur[illegible]. Some of the gas lamps on the bridge are necess[illegible] in order to fulfil the terms of an Act of [illegible] which requires that there should be a light [illegible] each arch, so as to facilitate the navigation [illegible] absence of these gaslights would have been an ad[illegible] the electric light by allowing the Jabloc[illegible] lamps to present a better *tout ensemble*. But of [illegible] vertical [illegible] of the latter there can be no doubt, [illegible] it to the vehicular as well as the pedest[illegible] over the bridge was evident. The whole [illegible] lamps are retained on the bridge, as it is not [illegible] at present to maintain the electric light after [illegible] period when the four candles contained in each lamp [illegible] burned out, which is some little time after midnight. The illuminating power of each of the electric lamps is estimated at 400 sperm candles, subject to a certain percentage of loss consequent on the use of frosted globe. The latter, however, allows a much larger proportion of light to pass through than occurred when the opalescent globes were employed, as in the earlier experiments on the Embankment, the Holborn Viaduct, and elsewhere. A remarkable fact connected with the Embankment trials is the increasing efficiency of the Gramme machines which generate the electricity. There appears to be no doubt that these machines are electrically improved by use, probably owing to the increase in the amount of residual magnetism. Other causes operate in the same direction, as, for instance, the diminished friction of the machinery as the working parts become more adapted to their functions. The Jablochkoff candles have also undergone some improvement. At all events, the encouraging fact is now stated that the engine has lately been maintaining forty lights with an indicated horse-power which is slightly less than that which was formerly required for twenty lights.

The total length of conducting wire now in use for the whole of the Embankment, together with Waterloo Bridge, is 17 miles 361 yards. When the Board-room at Spring-gardens is fitted up, the total length will be about 18½ miles. The lighting of the Embankment by this system commenced on December 13th last year, since which date 28,000 of the Jablochkoff candles have been consumed. M. Berly purposes making some experiments shortly with electric candles of large dimensions, giving lights equal to from 2,000 sperm candles up to 6,000, thus showing that the Jablochkoff system can give a highly concentrated light if desired.

53

Edison and the Electric Light.—Following up what appeared in our last Saturday's issue with reference to Mr. Edison and the electric light, we insert the following telegram from Philadelphia, which was contained in the *Times* of Monday last:—

Spending Saturday and Saturday night at Menlo-park with Mr. Edison, I thoroughly examined his inventions in electric lighting, comprising four particulars—generator, lamp, meter, and regulator—and providing, in my opinion, a complete substitute for gas. The light produced will be both cheaper and better than gas, being more regular and emitting so little heat that there is no danger of fire. Some of his lights are purposely fixed amid the most inflammable material. I lited igniting paper by them, but the paper remained unscorched. About 60 lights were burning. On Saturday night I saw them burn seven hours. Two have been burning continuously for ten days without injury to the baked cardboard horseshoe in the little glass globe which furnishes the light. Cardboard seems sufficiently durable, successfully resisting quite rough usage, such as dropping, shaking, turning the current on and off thousands of times, and raising the intensity of light to that of 400 candles. All the arrangements are simple. Mr. Edison will put about 800 lights at Menlo-park, while the inventions immediately go into practical operation in New York city. The globe containing the horseshoe is exhausted to one-millionth of an atmosphere by the Sprengel pump, measured by the M'Leod guage. By successfully dividing the electric current Mr. Edison gets individual lamps of 16-candle power, each lamp having 100 ohms resistance. Light is turned on or off, and the current regulated with the same ease as gas is, while the current can be transmitted on wire as small as No. 36. The central regulator maintains an even current, while the meters accurately measure the supply furnished to each consumer. Mr. Edison finds that the best generators are of five to seven horse power, each one-horse power maintaining eight lamps. Each lamp costs about one shilling to manufacture, while a supply equivalent to 10,000ft. of gas can be produced for tenpence or less. Mr. Edison calculates the cost of furnishing light thus—the consumption of 3lb. of coal in a steam engine will maintain eight to ten lamps one hour. Mr. Edison's system also furnishes electric power for small industries such as running sewing machines. Mr. Edison's light is bright, clear, mellow, regular, free from flickering or pulsations, while the observer gets more satisfaction from it than from gas. Mr. Edison lights at Menlo-park dwellings, offices, desks, street lamps, also laboratory and workshop, making it available for every lighting purpose for which gas is used. I ate my supper and wrote a draft of this telegram by Mr. Edison's light last night.

Telegraphic Journal Jan 15 1880

TRIALS OF THE JABLOCHKOFF AND WERDERMANN ELECTRIC LIGHTS IN PARIS.

SOME trials of the Jablochkoff and Werdermann Electric Light systems have recently been made at the French National Opera House, Paris. The experiments took place in the Opera *foyer*, or green-room, in the presence of a large number of persons interested in the result of the trials. The object in view was the comparison of the two systems.

Ten chandeliers were taken for the experiments, four being lighted by each system and the remaining two by gas.

"The first experiments were made with the Jablochkoff system, the candles being covered with yellowish coloured glass globes was to cut off as much as possible the violet rays which characterise the light when obtained by the voltaic arc. "The result," says *L'Estafette*, "was to bring out all the defects of the system, as the light continually flickered, changed colour, and produced a disagreeable noise. The Werdermann light, on the contrary, was perfectly steady and quiet in character, but from the absence of glass globes was not quite so warm in tone as its rival. This, however, was an intentional defect, as Mr. Werdermann purposely exposed the light in a naked state so that its natural warmth might be seen; of course, a globe slightly coloured only would tone down the light to the required tint."

As regards steadiness and noiselessness, the Werdermann light unquestionably carried the day. As regards economy, it may be stated that the 12 Werdermann lamps (three for each chandelier) were produced by a steam engine of 6 horse-power, constructed by Hermann-Lachapelle; the 8 Jablochkoff candles (two to each chandelier) were produced by a 12 horse-power Calla engine. The dynamo machine for the Jablochkoff system was turned at a higher velocity than that for the Werdermann system; a difference requisite in consequence of the Jablochkoff candles requiring intensity currents, whereas the Werdermann lamps are worked by quantity currents. This latter fact, although to the advantage of the Werdermann system when the lamps are placed close to the source of power, is a disadvantage when the two elements are distant one from the other, as very thick and expensive conducting wires would be required. Experiments made with the Werdermann light have shown that 5 lights, equal to 25 to 30 gas jets, may be obtained with a 1 horse-power engine.

The outlay incurred by using the Werdermann system is considerably less than that necessitated by the adoption of the Jablochkoff light, and this is no insignificant gain. It remains now for M. Garnier, the architect of the Opera house, to make his report to Government concerning the two systems, and to indicate which, after mature reflection, has the superiority. The result will be looked for with interest.

VOL. XXX.

EDISON'S EFFORTS.

Commercial

A Detailed History of His Recent Experiments.

HIS NEW ELECTRIC LIGHT.

In What It Differs from Other Lamps—He Claims to Have Surmounted All Difficulties.

The near approach of the first public exhibition of Edison's long-looked-for electric light—announced to take place on New Year's Eve at Menlo Park, on which occasion that place will be illuminated with the new light—has revived public interest in the great inventor's work, and throughout the civilized world scientists and people generally are anxiously awaiting the result. From the beginning of his experiments in electric lighting to the present time Mr. Edison has kept his laboratory guardedly closed, and no authoritative account (except that relative to his first ... published some months ago in the New York *Herald*) or any of the important steps of his progress have been made public. This course the inventor found absolutely necessary ... enabled by special ... to present to our readers a full and accurate account of his work from its inception to its completion. Edison's electric light, incredible as it may appear, is produced from a little piece of paper—a tiny strip of paper that a breath would blow away. Through this little strip of paper is passed an electric current, and the result is a bright, beautiful light, like the mellow sunset of an Italian autumn.

"But paper instantly burns, even under the trifling heat of a tallow candle!" exclaims the skeptic; "and how, then, can it withstand the fierce heat of an electric current?" Very true; but Edison makes the little piece of paper more infusible than platinum, more durable than granite, and this involves no complicated process. The paper is merely baked in an oven until all its elements have passed away, except the carbon framework. The latter is then placed in a glass globe, connected with the wires leading to the electricity-producing machine, and the air is exhausted from the globe. Then the apparatus is ready to give out a light that produces no deleterious gases, no smoke, no offensive odors; a light without flame, without danger; requiring no matches to ignite, giving out but little heat, vitiating no air, and free from all flickering; a light that is a little globe of sunshine, a veritable Aladdin's lamp; and this ... the inventor claims, can be produced cheaper than the cheapest oil.

Were it not for the phonograph, the quadruplex telegraph, the telephone and the various other remarkable productions of the great inventor, the world might well hesitate to accept his assurance that such a beneficent result had been obtained; but, as it is, his past achievements in science are sufficient guarantee that his claims are not without foundation, even though for months past the press of Europe and America has teemed with dissertations and expositions from learned scientists ridiculing Edison, and showing that it was impossible for him to achieve that which he had undertaken.

HISTORY OF ELECTRIC LIGHTING.

Before going into a description of Edison's experiments, it may not be uninteresting to briefly review the history of electric lighting, in general, pointing out at the same time the leading principles underlying electricity as a medium for illumination. Among its other properties, electricity has that of developing heat. A substance through which an electric current is made to flow, becomes heated in a degree proportioned, first, to the strength of the current, and second, to the size and character of the substance. Substances which readily convey electricity, or, in other words, which offer but little resistance to the passage of the electric current, such as copper, silver or iron, are unsuitable for exhibiting the heating power of electricity, while substances which offer much resistance to the passage of the current, such as platinum or carbon, show this heating power quite strongly. Either of the latter substances becomes heated to incandescence when a strong current of electricity is passed through them, which incandescence gives out a beautiful and pleasant light. This method of obtaining light from electricity has been known for many years, and is called the incandescent method. A second method, known as the Voltaic arc method, from Volta, an eminent electrician, is the passing of a powerful electric current between the points of two sticks or rods of carbon, slightly separated from each other. The passage of the current between the two causes an intensely brilliant light, many times more intense than that produced by incandescence. It is estimated to be about one-half the intensity of sunlight on a clear day.

The accompanying illustration shows the form of the Voltaic arc playing between the points of two carbon rods. When carefully studied on a screen—for the brilliancy of the light prevents its unshaded observation by the naked eye—there will be seen hosts of little jets of carbon, constantly passing in the form of an arc between the two carbon points. The problem, then, of utilizing electricity for the purposes of illumination presents two avenues of attack—one by way of the Voltaic arc, or intense light, and the other by way of incandescence, or milder light.

VOLTAIC ARC.—Considering first the Voltaic arc system, we find that as early as 1840 it began to attract the attention of inventors. Probably its first use outside of the laboratory and class-room was in the year 1846, when it was employed at the opera in Paris to produce the effects of the rising sun. Its success in this role was so satisfactory that before long enterprising managers had extended its field of usefulness by means of lenses and prisms to the production of luminous fountains, artificial rainbows and lightning. At this period, however, facilities for obtaining steadiness and uniformity of the light were exceedingly crude, and some mechanical device to keep the carbons at the same relative distance from each other was indispensable. The first contrivance, or regulator, as it was called, for this purpose was made in 1845 by Wright of London, and consisted of discs of carbon, having their circumference cut to a V shape, and receiving motion from well-known mechanism. The following year Staite and Edwards in London patented several regulators, the principle underlying them being the inclosing of the carbons in small cases, which made the carbon-points meet obliquely. In 1848, Foucault in France and Petrie in England made further improvements, by which the adjustment of the carbons was made quite reliable. Then followed numerous others, extending to the present time, of more or less perfection. Among these may be mentioned Archereau's, Lacassagne's, Thiers', Serrins', Duboscq's, Fauler's, Brush's, Maxim's and Fuller's. In the year 1876 a new departure in the form of regulators was made by M. Jablochkoff, a Russian engineer, who, instead of placing the carbon rods vertically to each other, placed them side by side, with a thin insulating substance between. In this form, the Voltaic arc playing between the extremities of the carbons gradually consumed them downward, like a flame consumes a candle. Indeed, so analogous was the invention to a candle that it soon became known as the Jablochkoff candle, a name it still bears. The incandescent method of electric lighting was first successfully shown by King in 1845. He placed a rod of carbon in a globe of glass, from which the air had been extracted, and passing a current of electricity through the rod caused it to become heated to such a degree that one could read large print a considerable distance away by the light emitted. His labors, however, were productive of no practical results, and while his theory for producing light was regarded as a pretty one, few were so bold as to predict that it would ever develop into an economical and efficient method of illumination.

THE USE OF NITRO-MURIATIC ACID.

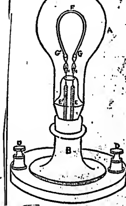
The following year Greene and Staite filed a patent for a lamp analogous to that of King, pointing out that they freed the carbon, before use, from impurities, by treating it with nitro-muriatic acid. In 1849 Petrie obtained patents for the same purpose, concerning which he wrote as follows: "A light may be produced by passing an electric current through a short and thin conductor, which heats and becomes luminous, but the majority of substances fuse and burn rapidly. However, I obtain a good light by using iridium or one of its alloys. Iridium may be fused so as to produce an ingot, whilst it is submitted to the heat of the Voltaic arc; afterwards it may be decarbonized and rendered more malleable. It can be cut into small pieces that can be fixed upon two insulated metallic supports, which are in connection with the two wires of a battery. Then there is produced a beautiful light." From this time until 1878 electric lighting by in-

The Sun

candescence made little progress, inventors regarding the incandescent method as much inferior to that of the Voltaic arc. In the latter year, however, interest in the incandescent method was a little revived by an invention of M. Lodyguine, who made a lamp that overcame many of the difficulties previously deemed insurmountable. Concerning this invention the report to the Imperial Observatory of Paris said: "The sole inconvenience of the use of carbon instead of platinum consists in the fact that in the combustion the carbon combines with the oxygen of the air, and is thus gradually consumed. M. Lodyguine has avoided this inconvenience by inclosing the carbon heated to whiteness by the electric current in a glass vacuum hermetically sealed, and from the interior of which the oxygen is expelled by a most simple process." But improved as was this arrangement over those that had gone before, practice demonstrated that there were still many serious difficulties it did not excel. "Among other things, the carbons presented obscure spots, indicative of non-homogeneity, minute cracks also occurred in the carbon and rapidly disintegrated the same. The vacuum likewise was very imperfect, and there was produced within the glass globe a kind of evaporation, that tended to slowly destroy the carbon rods. The evaporation also left a pulverised deposit of sublime carbon on the inside of the glass globe. Within the past few years various English and American inventors have overcome many of these difficulties, but there still remained enough to render incandescent electric lighting impracticable. While inventors were busy, both on the Voltaic arc and incandescent methods, progress was far from slow on the means for producing or generating the electric current.

PRODUCING ELECTRICITY BY THE ROTATION OF MAGNETS.

At an early day it was evident to experimenters that to produce the Voltaic arc or incandescence with any degree of economy, a different method of generating the electricity than that afforded by the chemical batteries in use was necessary. An important discovery by Ampere in 1820, developed almost simultaneously by Oersted and Arago, and later by Faraday, to the effect that powerful currents of electricity could be produced by the rotation of magnets near each other, opened an opportune field for purposes of electric lighting. Pixii, a manufacturer of physical instruments in Paris, in 1832, was first to practically apply the discovery. He constructed a machine consisting of an electro-magnet and a permanent magnet, with mechanism for revolving one directly in front of the other, which revolution induced strong currents of electricity that could be carried off by wires and made to give light. The invention of Pixii was followed by improvements by Nianel, Holmes, Ladd, Wilde and Siemens, and in late years by Gramme, Fuller, Brush, Holcomb, Maxim and others. The invention of Gramme, owned and used exclusively in this country for the Voltaic arc system by the Fuller Electrical Company, involved several important new principles that gave a marked impetus to the system and made possible the production of torrents of electricity at a comparatively small cost.



EDISON'S COMPLETED LAMP.

Edison began his experiments in September, 1878. His self-appointed task was to produce a pure, steady, reliable light from electricity on a scale of cheapness that would enable it to compete with gas for purposes of general illumination. He chose the incandescent system as his field of operations. His experiments with platinum were countless, and involved the invention of many mechanisms to aid the work. For two months he toiled day and night, only to find that as he had been using platinum it was entirely worthless for incandescent lighting. He arrived at the true cause of its defects, and hastened to apply the remedy. "I have found," he writes, "that when wires or sheets of platinum, iridium or other metallic conductors of electricity that fuse at a high temperature are exposed to a high temperature near their melting point in air for several hours by passing a current of electricity through them, and then are allowed to cool, the metal is found to be ruptured, and under the microscope there are revealed myriads of cracks in various directions, many of which reach nearly to the center of the wire. I have also discovered that, contrary to the received notion, platinum or platinum and iridium alloy loses weight when exposed to the heat of a candle; that even heated air causes it to lose weight; that the loss is so great, a hydrogen flame is tinged green. After a time the metal falls to pieces, hence wire or sheets of platinum or platinum and iridium alloy, as now known in commerce, are useless for giving light by incandescence; first, because the loss of weight makes it expensive and unreliable and causes the burner to be rapidly destroyed; second, because its electrical resistance changes by loss in weight, and its light-giving power for the total surface is greatly reduced by the cracks or ruptures."

DISCOVERIES CONCERNING PLATINUM.

"The melting point also is determined by the weakest spot of the metal. By my invention or discovery, I am able to prevent the deterioration of the platinum or its alloys by cutting off or intercepting the atmospheric action. A spiral wire, or other form of platinum, is placed in a glass tube or bulb, with the wire near its ends, passing through and sealed in the glass, and the air is exhausted from the glass. The platinum wires of the spiral are then connected to a magneto-electric machine or battery, the current of which can be controlled by the addition of resistance. Sufficient current is allowed to pass through the wire to bring it to about 150 degrees Fahrenheit. It is then allowed to remain at this temperature for ten or fifteen minutes. While thus heated, both the air and gases confined in the metal are expelled by the heat or withdrawn by the vacuum action. While this air or the gases are passing out of the metal, the mercury-pump is kept continually working. After the expiration of about fifteen minutes, the current passing through the metal is augmented so that its temperature will be about 300 degrees Fahrenheit, and it is allowed to remain at this temperature for another ten or fifteen minutes. The mercury-pump is to be worked continuously, and the temperature of the spiral raised at intervals of ten or fifteen minutes until it attains vivid incandescence, and the glass is contracted where it has passed to the pump and melted together, so that the wire is in a perfect vacuum and in a state heretofore unknown, for it may have its temperature raised to a most dazzling incandescence, emitting a light of twenty-five standard candles, whereas before treatment the same radiating surface gave a light of only about three standard candles. The wires, after being thus freed from gases, are found to have a polish exceeding that of silver, and obtainable by no other means. No cracks can be seen even after the spiral has been raised suddenly to incandescence many times by the current, and the most delicate balance fails to show any loss of weight in the wire, even after it has been burning for many hours. ... I have further discovered that if an alloy of platinum and iridium, coated with the oxide of magnesia, be subjected to the vacuum process described, a combination takes place between the metal and the oxide, giving the former remarkable properties. With a spiral having a radiating surface of three-sixteenths of an inch, light equal to that given by forty standard candles may be obtained, whereas the same spiral not coated by my process would melt before giving a light of four candles. The effect of the oxide of magnesia is to harden the wire to a surprising extent and render it more refractory. A spiral made of this wire is elastic and springy when at high incandescence. I have found that chemically-pure iron and nickel, drawn in wires and subjected to the vacuum process, may be made to give a light equaling that of platinum in the open air. Carbon sticks also may be freed from air in this manner and be brought to a temperature where the carbon becomes pasty, and on cool-

y Chronicle

ing it is homogeneous and hard." About this time another truth dawned on the inventor, namely, that economy in the production of light from incandescence demanded that the incandescent substance offer a very great resistance to the passage of the electric current.

One by one Mr. Edison had overcome the many difficulties that lay in his path. He had brought up platinum as a substance for illumination from a state of comparative worthlessness to one of well-nigh perfection. He had succeeded by a curious combination and improvement in air-pumps in obtaining a vacuum of nearly one-millionth of an atmosphere, and he had perfected a generator or electricity-producing machine (for all the time he had been working at lamps he was also experimenting on magneto-electric machines) that gave out some 90 per cent in electricity of the energy it received from the driving engine. In a word, all the serious obstacles toward the success of incandescent electric lighting he believed had melted away, and there remained but a comparatively few minor details to be arranged before his laboratory was to be thrown open for public inspection, and the light given to the world for better or for worse. There occurred, however, at this juncture a discovery that materially changed the system, and gave a rapid stride toward the perfect electric lamp. Sitting one night in his laboratory, reflecting on some of the unfinished details, Edison began abstractedly rolling between his fingers a piece of compressed lampblack, mixed with tar, for use in his telephone. For several minutes his thoughts continued far away, his fingers meantime mechanically rolling out the little piece of tarred lampblack, until it had become a slender filament. Happening to glance at it, the idea occurred to him that it might give good results as a burner, if made incandescent. A few minutes later the experiment was tried, and, to the inventor's gratification, satisfactory, although not surprising, results were obtained. Further experiments were made with altered forms and composition of the substance, each experiment demonstrating that at last the inventor was upon the right track. A spool of cotton-thread lay on the table in the laboratory.

A MARVELOUS DISCOVERY.

The inventor cut off a small piece, put it in a groove between two clamps of iron, and placed the latter in a furnace. The light obtained from the tarred lampblack had convinced him that filaments of carbon of a texture not previously used in electric lighting were the hidden agents to make a thorough success of incandescent lighting, and it was with this view that he sought to test the carbon remains of a cotton thread. At the expiration of an hour he removed the iron clamps containing the thread from the furnace, and took out the delicate carbon framework of the thread—all that was left of it after its fiery ordeal. This slender filament he placed in a globe and connected it with the wires leading to the machine generating the electric current. Then he extracted the air from the globe and turned on the electricity. Presto! a beautiful light greeted his eyes. He turns on more current, expecting the fragile filament instantly to fuse; but no, the only change is a more brilliant light. He turns on more current, and still more, but the delicate

5-3-

thread remains on ... Then, with characteristic impetuosity, and marveling at the strength of the little filament, he turns on the full power of his machine and eagerly watches the consequences. For a minute or more the tender thread seems to struggle with the intense heat (passing through it—heat that would melt the diamond itself—then it quivers and succumbs and all is darkness. The powerful current had broken it in twain, but not until it had emitted a light of several gas-jets. Eagerly the inventor hastened to examine under the microscope this curious filament, apparently so delicate, but in reality much more infusible, when in a vacuum, than platinum, so long considered one of the most infusible of metals. The microscope showed the surface of the filament to be highly polished, and its parts interwoven with each other; it was also noticed that the filament had obtained a remarkable degree of hardness compared with its fragile character before it was subjected to the action of the electric current. Night and day, with scarcely rest enough to eat a hasty meal or catch a brief repose, the inventor kept up his experiments and from carbonizing pieces of thread he went to splinters of wood, straw paper and many other substances never before thought of for incandescent lighting. The results of his experiments showed that the substance best adapted for carbonization, and the giving out of incandescent light, was paper, preferably thick like card-board, but giving good satisfaction even when very thin. The beautiful character of the illumination and the steadiness, reliability and non-infusibility of the carbon filament, were not the only elements incident to the new discovery that brought joy to the heart of Edison. There was a further element not the less necessary because of its being hidden, the element of a proper and uniform resistance to the pressure of the electric current. The inventor's efforts to obtain this element had been by far the most laborious of any in the history of his work, and without it absolute success to electric incandescent illumination could not be predicated, even though all the other necessary preparations were present in the fullest degree.

EDISON'S PERFECTING LAMP.

Passing over the scores of experiments made since the discovery that the carbon framework of a little piece of paper or thread was the best known substance for incandescent lighting, we come to consider the way in which the same is prepared at the present time in the Menlo Park laboratory. With a suitable punch there is cut from a piece of "Bristol" card-board a strip of the same, in the form of a miniature horseshoe about two inches in length and one-eighth of an inch in width. A number of these strips are laid flatwise in a wrought-iron mold about the size of the hand, and separated from each other by tissue paper. This mold is then covered and placed in an oven, where it is gradually raised to a temperature of about 600 degrees Fahrenheit. This allows the volatile portions of the paper to pass away. The mold is then placed in a furnace and heated almost to a white heat, after which it is removed and allowed to cool gradually. On opening the mold the charred remains of the little horseshoe card-board are found, and must be taken out with the greatest care, else it will fall to pieces. After being removed from the mold it is placed in a little globe and attached to the wires leading to the generating apparatus. The globe is then connected with an air-pump, and the latter is at once set to work extracting the air. After the air has been extracted the globe is sealed and the lamp is ready for use. The accompanying illustration shows the lamp complete. A is a glass globe from which the air has been extracted, resting on a stand, B. F is the little carbon filament connected by fine platinum wires g 1, g, to the wires E E leading to the screw posts D 1, D, and thence to the generating machine. The current entering at D passes up the wire E to the platinum clamp G, thence through the carbon filament F to G 1, down the wire E 1, to the screw-post D 1, thence to the generating machine. It will be noticed by reference to the illustration of the complete lamp that it has no complex regulating apparatus, such as characterized the inventor's earlier lamps. All the work Edison has done in regulators was practically wasted, for he had only then realised that they were not at all necessary, no more so than a fifth wheel is to a coach. He finds that the electric current can be regulated with entire reliability at the central station just as the pressure of gas is now regulated. By his system of connecting the wires, the extinguishment of certain of the burners affects the others no more than the extinguishment of the same number of gas-burners affects those drawing their supply from the same main. The simplicity of the completed lamp seems certainly to have arrived at the highest point, and Edison asserts that it is scarcely possible to simplify it more. The entire cost of construction is not more than twenty-five cents. The lamp shown in the illustration is a table-lamp. For chandeliers it would consist of only the vacuum globe and the carbon filament attached to the chandelier, and connected to the wires leading to the generating machine in a central station, perhaps half a mile away, the wires being run through the gaspipes, so that, in reality, the only change necessary to turn a gas-jet into an electric lamp, is to run the wires through the gaspipe, take off the jet and screw the electric lamp in the latter's place. Although the plans have not yet been fully consummated for general illumination, the outline of the probable system to be adopted is the locating of a central station in large cities, in such a manner that each station will supply an area of about one-third of a mile. In each station there will be, it is contemplated, one or two engines of immense power, which will drive several generating machines, each generating machine supplying about fifty lamps.

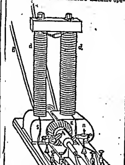
THE GENERATING MACHINE.

Mr. Edison's first experiment in machines for generating the electric current did not meet with success. His primal apparatus was in the form of a large tuning-fork, constructed in such a way that its ends vibrated with great rapidity before the poles of a large magnet. These vibrations could be produced with comparatively little power. Several weeks of practice proved, however, that the machine was not practical, and it was laid aside. Then,

SAN FRANCISCO

2-2-1879

followed a number of other forms, leading up gradually to the one at present used. Bearing in mind the principle common to all magneto-electric machines, viz., that the current is produced by the rotation of magnets near each other, it will not be difficult to understand in a general way how Edison's machine operates.



THE FARADAY OR GENERATING MACHINE.

The preceding illustration shows the generating or Faraday machine, as Edison terms it, in honor of Faraday, complete. A A are two upright iron columns three feet high and eight inches in diameter, wound with coarse wire, and resting upon the base, N and S, which form its magnetic poles. This part of the apparatus is called the field of force-magnets. Fixed on an axle so as to freely revolve between the poles N and S, is a cylinder armature of wood, E, wound parallel to its axis with fine iron wire. When this cylinder or armature is made to revolve rapidly between the magnetic poles N and S, by means of the belt B, driven by an engine (not shown in the cut), there is generated in the wire surrounding the armature E strong currents of electricity, which are carried off by the wires W W to the electric lamps. The apparatus for measuring the amount of electricity used by each householder is a simple contrivance, consisting of an electrolytic cell, and a small coil of wire appropriately arranged in a box, the latter being about half the size of an ordinary gas meter, and, like a gas meter, it can be placed in any part of the house. The measurement is obtained by the deposit of copper particles on a little plate in the electrolytic cell, such deposit being caused by the electric current passing through the cell. At the end of any period, say one month, the plate is taken by the inspector to the central office, where the copper deposit is weighed, and the amount of electricity consumed determined by a simple calculation. In addition to the various parts of the system above described, there are a number of other details, not so important, to be sure, as those of which sketches have been given, but nevertheless essential to make up the complete plan of economical electrical illumination. A description of these latter will not be attempted, as a proper understanding of them involves a technical knowledge of the laws of electricity. The entire system embraces an amount of work so extensive that one naturally wonders how a single man, in such a brief space of time as fifteen months, could possibly have planned out and perfected it all; and the surprise becomes greater when it is considered that during this period Edison found time to make other inventions. A sextuple telegraph, or apparatus for sending six messages on one telegraph wire in opposite directions simultaneously, saw light during the progress of the electric light, patents for the same having only just been issued.

EDISON'S INVENTION FOR EXTRACTING GOLD FROM "TAILINGS."

Several new and important improvements in his chalk telephone, by which the efficiency of that invention is greatly increased, also attest his industry and versatility of genius. But perhaps the latter quality is more strikingly exhibited in his Polyform, a preparation by which he is enabled to bid defiance to sick headaches, neuralgia and other nervous diseases, and to make himself largely independent of physicians in times of ailment. The Polyform grew out of necessity. Being considerably afflicted with neuralgia and obtaining no relief from his physician, Edison set out to become his own doctor. His chemical laboratory, one of the most complete in the United States, furnished him an ample field from which to draw. Experiment followed experiment, the inventor becoming more determined in proportion as his neuralgia grew more painful. At last he obtained a combination of chemicals, a slight application of which to the face, immediately relieved his pain. Gratified at his success, but hardly yet convinced, he tried the application on others similarly affected, and with equally satisfactory results. About this time there happened to stroll into the laboratory one day a tramp on his periodical begging expedition from place to place. Now this tramp was a particularly unfortunate one, his poverty being hardly more distressing than his physical ailments. One of his jaws was swelled with rheumatism, neuralgia coursed along his face, and a dozen or more sores and bruises made him a veritable Job. Edison saw in him a most excellent subject for further polyform experiments. A hearty meal and a little cash readily procured the tramp's consent, and soon the inventor was subjecting his new acquaintance to all sorts of chemical experiments. For more than a week the tramp found food and lodging in Menlo Park, giving in return a few hours of his time every night to be experimented upon. By the time his engagement was over his rheumatism and neuralgia had disappeared and his sores were well-nigh healed. The news of the tramp's good fortune soon spread, and now it is no uncommon thing for neighbors to come to the inventor's laboratory from miles around to request a little polyform, a request which the inventor good naturedly complies with. The very, very latest enterprise of the indefatigable scientist is a scheme for obtaining gold out of "tailings," or the sand thrown away by refiners as having been worked out. It is said that Edison has succeeded in obtaining a chemical preparation which will take from $200 to $800 per ton out of "tailings," from which the present processes can obtain nothing. The matter, however, is as yet a profound laboratory secret.

Recent Advances in Electric Lighting.

By J. N. SHOOLBRED, C.E.

THE author said that twelve months ago very little was, comparatively speaking, known of the electric light, whereas now there was no town in England of any magnitude in which experiments had not been made. The progress in the electric light had been very great. The great desideratum was the production of a number of smaller lights of less intensity in place of producing one light only of great intensity, and great progress had been made towards the solution of the difficulty. The question of the relative sanitary effects of the illumination by electricity and also by gas had received considerable attention, and the result had been considerably to the advantage of electric illumination. The author then gave an explanation of the various processes of electric lighting now in vogue, in the course of which attention was drawn to the lamp of M. Heinrich, a description of which we illustrate elsewhere.

PUBLIC LEDGER
AND DAILY TRANSCRIPT.
Philadelphia, Monday, Dec. 29, 1879.

MENLO PARK LIGHTED.

Seven hours with Mr. Edison, at Menlo Park, were spent by a representative of the LEDGER on Saturday, and what the latter has to say on the subject of the electric light will be found in another column. It will be remembered by those who keep track of progress in this very interesting matter that when public announcement was made that Mr. Edison had found the right material for his incandescent electric lamp—by using a thread-like loop of charred or carbonized pasteboard—a challenge came from a skeptical expert in electric lighting that Edison could not keep a light going for three hours in a lamp so constructed. How little force there was in that criticism was brought visibly to the notice of our representative, for he saw a number of the new electric lamps burning for a period of seven hours on Saturday. This much he witnessed, and was told, what he had no reason to doubt, that some of them had been in operation for two weeks.

In order to explain the present condition of the effort to use electricity for ordinary purposes as an illuminating agent, we shall have to recall a few points to the memory of the reader. That electricity is convertible into light was known long ago; that it was possible to utilize the light so produced for illumination as a substitute for oil, candles or gas, is a piece of knowledge that dates back more than a generation. But because of many difficulties, this use of electricity has never been brought into practice in a general way, until within a few years. The chief difficulties were these: first, the electric current passing along a wire leading to an electric lamp, was not divisible so as to feed a number of lamps each of the capacity of an ordinary gas jet; but, instead of these, there was one dazzlingly-bright light, far more intense than was needed for a limited space like the interior of a building; second, the light was fitful and uncertain, instead of being steady like a gaslight; third, when any substance was consumed in getting the light, such as the carbon sticks of the "Jablochkoff candle" and other equivalent devices, another element of difficulty was introduced requiring delicate mechanism to overcome, or alternating currents of electricity, or something of the kind; fourth, none of the lights were manageable like gas jets in regard of being turned up or down to regulate the degree of light needed; and, fifth, all of the lights were more expensive, as well as less convenient than gas.

It was to overcome these chief difficulties, and many smaller ones, that Mr. Edison, in common with other ingenious men, set his wits to work. There are three forms in which the electric light has been used experimentally for illuminating purposes: the electric flame itself (or "arc," as it is called), which is produced when the current is forced to leap over a short break in the line of conducting substances; next, the light produced by the electric burning of a substance like carbon, in which the substance is actually consumed like a candle or lamp wick; and third, by "incandescence," or by heating some substance to a white heat, as when a rod of iron is thrust into a glowing fire and brought out white hot. Most of the recent work towards getting a practicable electric light for common use has been devoted to the first two of the forms mentioned—the electric arc and the burning candle. Mr. Edison devoted his experiments exclusively to the third—procuring a light by "incandescence," or heating some substance to a glowing white heat. This form got rid of many difficulties inherent in the others; but the problem was to find the substance that would stand the intense heat required without burning, melting, or otherwise disintegrating. He tried nearly every available substance, giving much time to platinum and its alloys with a promising degree of success; but finally settled upon the little strip, or thread rather, of charred pasteboard heated to an intense white heat in an exhausted glass bulb, as described in the account of our representative's visit to Menlo Park. This works so well that the laboratory and workshops at that place are lighted with this form of electric lamp, and several private residences besides. In fact the course of experiment seems to have reached that point where the mere laboratory study of the subject ends, and where the test of time and experience and growth by use begins. Any one may go to Menlo Park of nights this week and see parts of that place lit up by Edison electric lamps—lamps outdoors as well as indoors—lamps of the dimensions needed for household purposes and for street illumination. This is the condition now of Mr. Edison's inventions, which include many other things besides the substance and form of the lamp itself. Crucial tests are now to be applied—the test of time as to durability of the lamp—the test of experience in its manageability in actual use, and the money test, applied to its commercial economy. As to the first there is but little reason to apprehend failure, for the lamp is simple and inexpensive (costing but twenty-five cents), easily renewable, and renewable in case of wearing out or breakage by accident. As to the second, something more than has thus far been shown has yet to be done before the lamp can be considered as ready for universal use or as manageable as a gas-light. With regard to the third, or the comparative cheapness of the lamps compared with a gas-light, Mr. Edison claims that it need not cost more, at the outside, than half the average price of gas in the United States, but this question of cost remains to be demonstrated. Meanwhile, there are the houses and open spaces at Menlo Park actually lighted up, as the substance of the thing hoped for by those tired of the exactions of Gas Trusts and Gas Companies, and these any one may see wherever gas is used for the purposes of illumination; and meanwhile, also, it will no longer be in order for theoretical objectors, or the proprietors of "shops over the way," to be firing off their criticisms in the newspapers unless these first go to Menlo Park and see what is actually going on.

Public Ledger 12-29-79

EDISON'S ELECTRIC LIGHT.

A VISIT TO MENLO PARK—THE BUILDINGS ILLUMINATED WITH A MELLOW, STEADY LIGHT FROM SCRAPS OF CARDBOARD.

MENLO PARK, N. J., Dec. 27, 1879.

MR. EDITOR:—Writing the notes of this letter from Edison's office, by the light of his wonderful electric lamp, I am obliged to pronounce it satisfactory, and fitted in every way to take its place as the rival of gas—provided, of course, that it shall prove as cheap, or cheaper, as Mr. Edison declares it to be. The lamp is the most interesting feature of the apparatus employed, so that I shall describe it first, although, in logical sequence, it is the last of the four inventions which make up Edison's system of electric lighting.

EDISON'S LAMP AND THE LIGHT IT GIVES.

In most of the systems of electric lighting heretofore shown to the public, the light has come from the combustion of carbon in the voltaic arc. Two rods of carbon, between which the passage of the current sets up the arc, are gradually consumed, and require special machinery or its equivalent to maintain the ends or edges of the carbons in the same relative position. The light thus furnished is of very great candle power, from 400 to 2,000 or more, and is objectionable on that account, and entirely unfitted for use in dwellings. Edison has sought from the first to produce his light by incandescence, making either platinum or carbon white-hot, but without combustion, thus making the lamp more or less permanent, and doing away with machinery for regulation. The platinum lamp was abandoned a few weeks ago for one made of carbon, prepared in a peculiar way, and this carbon lamp is the one now exhibited at Menlo Park with great success.

HOW THE LAMP IS MADE.

A piece of cardboard (Bristol board) is cut in the shape of a horseshoe about two inches high and one and a quarter inches across. The horseshoe is about one thirty-second of an inch wide on its face, and is therefore very delicate looking even before it has been baked. Three of these horseshoes are put in an iron mould in alternate layers of blocks of carbon, the object being to keep them flat while they are being baked. The moulds or retorts are first baked at about 300 degrees Fahrenheit over a gas flame to drive the volatile matters from the cardboard, and are then put in a furnace, where they are raised to a white heat, and when removed ... till the iron box shows signs of being about to melt. They are then allowed to cool gradually, and, on being opened, the charred remains of the horseshoe are found. It has shrunk one-third in size and is now not more than an inch and a half in height, and about the thickness of a coarse horse hair. It is of course very delicate and has to be handled with care, but it is not likely to be broken except when an attempt is made to open the horseshoe by separating the two ends. It is then easily parted, but is reasonably tough when subjected to other movements. This fine piece of carbon, the equivalent, it is said, of ... three inches long, is to furnish Edison's electric light when made white hot by the passage of the electric current. It is mounted in a glass "globe," shaped like the air-chamber of a force pump, and when in position, the curved sides of the globe or bulb are almost parallel to the line of the horseshoe. The globe has a neck, through which wires pass, to which the horseshoe is attached by platinum clips. The bottom of the globe is sealed up with the wires, by a small bell-shaped structure of glass occupying the neck. Sprengel pumps are used to exhaust the air from the globe containing the horseshoe until McLeod's gauge shows a vacuum of one-millionth of an atmosphere has been reached. The globe having then been sealed, it is ready for use.

WHAT THE LAMP LOOKS LIKE.

As completed, the lamp is nothing more than a glass bulb, probably two and a half inches in diameter, having a neck extension, making the lamp in all about five or five and a half inches high. Inside of this we see wires leading up from the base, where they terminate in copper tips, to the almost invisible carbon horseshoe which connects them together. To light the lamp the copper strips at the bottom must be connected in some way with the wire in which the main current is passing. Then the electricity will pass up one wire through the carbon horseshoe, and down the other wire, making the carbon horseshoe red or white hot, according to the resistance it may offer. The resistance of most of the lamps in use here to-day was 100 ohms, but experiments are being made with lamps of higher resistance, and some of those exhibited reached 160 ohms. The lamps can be attached to the conducting wires in any position, and used in single lamps, gas ...

THOUGHTS' OBJECTIONS ANSWERED.

[illegible]

SMALL CONDUCTORS AVAILABLE.

One of the objections to electric lighting has been the alleged great cost of the conductors required for an extensive system. Mr. Edison, to show that very small wires would suffice to carry the current to single lamps, made attachments by means of No. 36 wire, which is probably as fine as a cambric thread, and the current passing through this served to light two lamps. No. 36 copper wire weighs about a quarter of a pound to the mile.

THE LAMPS IN POSITION.

Only temporary fixtures have been prepared for the electric lamps, these being generally made of existing gas fixtures, through which the service wires are run. These are provided with a screw button, with which contact is made or broken, and the light turned on or off. The lamps, as explained before, are complete in themselves, having been set in the cup in which the gas fixture, whatever its form, terminates, the turning of the button makes or breaks contact. With the rough fixtures now in use, it was not an easy matter to regulate the light, that is, to turn it down without extinguishing it, but there was no difficulty about either lighting the lamp or putting it out. As to that, it was quite as manageable as gas. It is, of course, very [illegible] that for the present, at least, the [illegible] of gas fixtures should be adopted in [illegible] with the electric light, but this is far from being necessary, as Mr. Upton, the mathematician at Menlo Park, has demonstrated. In his house, which is over thirteen hundred feet (a quarter of a mile) from the generator, the lamp in the hallway is suspended by the conducting wire from the ceiling, and hangs what may be called upside down, the globe being below the neck. Attached to the wire and concealing it, is a bunch of Pampas grass reaching to the globe. A plug attached by a short wire to the side of the tumbler being inserted in its place, closes the circuit, and instantly the overhanging lamp is ablaze with light. There is a similar arrangement in his parlor, the wire in this case being festooned with smilax and artificial flowers, forming a much handsomer chandelier than the most ornate of metal ornaments. In addition to this central light, Mr. Upton has two in opposite corners of the room, in the cove of the cornice. All of these lamps are lighted or extinguished at will by means of circuit-closing plugs, fastened, within easy reach, in the window frame. We visited Mr. Upton's house after dark, and he invited us to go out in the yard, to see how the wires were brought in from the laboratory. It was quite dark, but that proved no obstacle in our seeing. He brought with him one of the lamps, and, when he reached the wires, he simply hung the lamp to them, thus making the necessary connection, and it was instantly lighted. The wires were carried overhead to the house, and passed down into the house by the cellar window, under the floor, and up the walls inside, wherever necessity required that they should be carried.

EDISON'S OTHER INVENTIONS.

Although the lamp is a very important part of the system—the result for which every one looks—it would be of no practical value without the apparatus to generate the current, to regulate it and to measure the amount served to each consumer. The generator, the regulator and the motor have also been perfected, and are open to public view.

58

THE GENERATOR.

[illegible] is a dynamo-electric machine, not differing in essential features from others now in use, but still having points of difference which are said to make it much more efficient. Although the armature which revolves between the poles of a magnet is no larger than that of a Gramme machine, the magnet is very much larger and heavier, and this gives it a much different appearance from the Gramme or the Brush machines. The upright iron columns of the magnet are three feet high and eight inches in diameter, and each is wound with sixty-five pounds of coarse copper wire. The columns are united at the top by a heavy piece of iron weighing several hundred pounds and stand upon other equally heavy pieces forming the poles between which in the magnetic field the armature revolves. This armature is made of wood covered with fine wire wound parallel to its axes. The armature is revolved rapidly by steam power between the magnetic poles, and there is thus set up in the coil of wire surrounding the armature a uniform and constant current of electricity, which is carried off for use in lamps, or motors, by wire brushes connected with the "distributing main" or wire. Mr. Edison's generator does not appear to differ materially from other dynamo-electric machines except in the great weight of the magnets and the fact that they are charged from a separate machine. When a central office having many generating machines has been established, one will be used exclusively for charging the magnets of the others.

THE ELECTRIC MOTOR.

Intimately connected with this generator is the domestic motor, which is simply the generator reversed, the electric current being here converted into motion instead of motion into electricity. For convenience, the magnet of the motor is placed horizontally on the [illegible] and instead of vertically as in the generator. The resistance of the wire enclosing the magnet is made equal to that of one of the lamps, so that the use of the motor involves the consumption of no more electricity than is required for a lamp equivalent to a gas jet. In Mr. Edison's office there was a sewing machine attached to one of the domestic motors, the latter being placed in a box about eighteen by thirty inches and five or six inches high, behind the machine. When he desired to show the uses of the motor he removed an electric lamp from its socket in a table stand and inserted a wooden plug of similar shape carrying the wires of the motor. This established the connection, and the sewing machine started to run at full speed, which, however, [illegible] could be delicately regulated by a brake. [illegible] substitution of the lamp for the motor [illegible] wires instantly changed the manifestation [illegible] of electric force from motion to light. [illegible] again illustrate the divisibility of the current, Mr. Edison attached the wires of the motor to those leading to the lamp, and then we had the light and the work of the sewing machine at the same time. Another of these motors, said to be equivalent to a single lamp, is employed in the workshop to run a force pump.

THE REGULATOR.

This is intended to regulate the amount of current delivered to the lamps, so as to keep them at a constant degree of illuminating power. There is a galvanometer which indicates by a point of light on a graduated scale the amount of resistance offered. A certain point is taken as the standard at which resistance shall be maintained. As consumers turn on the electric light the point of light will move on the scale, and the man having charge of the regulator, by turning a wheel, compensates for the gain or loss of resistance by taking off or putting on resistance in the form of resistance coils. These are simply long coils or bobbins of wire, offering a known amount of resistance to the passage of the current. They are or may be put in circuit, and the resistance will vary according to the number and size of the coils through which the current passes. When the man at the wheel in the central office turns his wheel, which he does when the point of light moves on the scale, he simply increases or decreases the length of the circuit and brings the point of light back to its standard and so compensates for variations in the amount of electricity being used in the lamps. The galvanometer, with its point of light on a scale, serves a similar purpose to the piece of lead on the bellows of a church organ, indicating to him the rise and fall of resistances.

THE METER

is important to the company furnishing the electric light, that an accurate record may be kept of the amount of electricity consumed. It is very ingeniously constructed. One five-hundredth part of the electricity carried over the service wire of a house passes into an electrolytic cell, where it is set to work depositing copper on a plate. At the end of the month or quarter, when a bill is to be made out, the plate on which the copper has been deposited is taken out and a new one put in its place, the old plate being returned to the office, where it is weighed to ascertain the amount of copper deposited during the term. One gramme of copper deposited is to represent and be the equivalent of 1000 cubic feet of gas consumed, and when that much is deposited on the plate, it will show that electricity equivalent to 500,000 cubic feet of gas has passed into the house. No one yet knows what the charges are likely to be per gramme or milligramme of copper deposited.

ESTIMATES OF COST.

Mr. Edison says that estimates have been made of the cost of the electric light, which is far below that of gas, but these estimates are the property of the Electric Light Company, and he does not feel at liberty to make them public. The idea that experiments are conducted at Menlo Park haphazard, without regard to cost is a very erroneous one. By correspondence and an exhaustive examination of reports and statistics, there has been collected a vast amount of information about the cost of m[illegible] gas in different cities, and also the cost of horse power from large engines in manufactories here and in England. These figures and estimates have been tabulated by Mr. Upton, so that comparisons can be made [illegible] to the relative cost of gas and electric lighting. The statistics regarding the manufacture of gas in Paris, where the cost of making a thousand cubic feet of gas is comparatively small, are said to be very complete, enabling Mr. Upton to ascertain all the elements, and prove the results. While expressing his admiration for the fullness of these returns, Mr. Edison incidentally mentioned that he tried to get a report of the Philadelphia Gas Trust, but could make nothing out of it. He doubtless felt comforted when told that in that respect at least he resembled his Philadelphia visitors. Mr. Edison's argument to show, without committing himself to figures, that the electric light can be furnished more cheaply than gas is this:

The plant does not cost more than half that of gas works. The depreciation is less than half that of the plant of gas works. One pound of coal produces one standard gas jet, one hour, while Mr. Edison claims that three pounds of coal will [illegible] eight electric lights one hour, e[illegible] being equal to a single gas jet.

Another statement made by [illegible] of Mr. Edison's assistants is that the equivalent of 1000 cubic feet of gas can be [illegible] "for less than fifty cents and pay [illegible] per cent. interest on the plant."

Another statement is this:—"It is found economical to work generators requiring from five to seven horse-power to drive them, and to take from them about eight lamps per horse-power. A calculation based on this statement (but not by Mr. Edison) would make the cost of power alone equivalent to from 12 to 15 cents per 1000 cubic feet of gas. The cost of horse-power seems, however, to be an unknown quantity. Statistics as to this have been collected by Mr. Edison, and much stress is laid by his assistants on a return from a large cotton mill in Manchester, England, where the cost per horse power per hour is said to be only half a cent. Estimates from large manufactories in this country have been made (some of them for the Ledger), where the cost appears to be as high as 2½ cents per hour per horse power. On this depends much of the cost of the electric light, but supposing the other statements to be true, and the power to cost the higher sum (2½ cents), the power to produce light equivalent to that furnished by 1000 cubic feet of gas would cost 30 cents.

As to these matters it should be remembered, however, that I have only such information as was given to me by Mr. Edison and his assistants. There is no difficulty in the way of ascertaining the exact cost, and doubtless capitalists before they organize electric light companies, will have records kept of the amount of coal consumed, cost of attendance, &c., which alone can give reliable data. The rough calculations here made are only intended to show, that, if the statement is true, that eight lamps can be maintained for one horse power, the claim as to the relative cheapness of the electric light is not unreasonable.

One other thing must be remembered as helping to cheapen the cost. Interest on plant goes on night and day, whether the plant is earning money or not, but the general introduction of the electric motor, which is expected to be coincident with that of the electric light, would enable the plant to earn money day and night.

THE PLANT.

The engine, generators and conducting wires will represent the chief cost of the plant. The generators are to be made as cheaply as possible, without extra finish, and, although necessarily costly, will be sold "at a much less price than that now charged for dynamo electric machines." An experiment, described above, shows that the conducting wires need not be very large. These facts are the basis of the claim that the plant will cost only half that of gas works. As to the cost of maintenance being less, that is probably based on the fact that the most costly parts of the generators are not subject to much wear and tear. The lamps can certainly be made for twenty-five cents each, although the platinum clips alone cost 8 cents.

PLANS FOR THE FUTURE.

Mr. Edison is now building six new generators, one of which was completed and set at work on Saturday, taking the place of an earlier one that was not doing satisfactory work. About twenty-five lamps are made daily, and these are put in use as soon as completed. It is Mr. Edison's expressed intention to put his generators and lamps at work as soon as they are completed, until he has probably 800 lamps burning night and day in Menlo Park. If the lamps burn continuously for a month without accident, Mr. Edison thinks they will have seen the service required of them in six months of average use. They will then be tested to see whether the carbon horseshoes have undergone any change in resistance, and if not, he will feel satisfied that they can be made to last for years. As heretofore stated, one of the lamps has been burning almost continuously for two weeks. This alone represents probably two months' of average use. Work is carried on night and day at the laboratory and workshop, the greater part of the work being done at night, the only time when the laboratory and workshops are free from visitors. It is said that before spring an office will be opened near Madison Square, New York, and the houses in that vicinity lighted with electricity to demonstrate in practice the value of the new system. The Electric Light Company expects to sell rights in the principal cities, and will institute this experiment to demonstrate the practicability of the invention. It is also reported that prior to that demonstration a room in New York will be lighted from the generators at Menlo Park, twenty-four miles away, the current being carried over a Western Union wire.

MENLO PARK AND MR. EDISON.

I have written so much about the electric light that I can spare only a few words for a subject of interest only inferior to that—Menlo Park and its proprietor. Mr. Henry H. Bentley, [illegible] electrician, of this city, and a warm friend of Mr. Edison's, escorted the representatives of the LEDGER and London Times to Menlo Park, and it was through his assistance that we were enabled to make a thorough examination of everything about the place. Menlo Park is a few miles above New Brunswick, on the Pennsylvania Railroad line to New York. It exists only because of Edison's home and workshops being there. The buildings comprise seven workshops, &c., some of them very large, three handsome dwellings, belonging to Mr. Edison and his assistants, and a few smaller ones, occupied by workmen. What is known as the laboratory is a very large two-story frame building, and, with the brick workshop, engine house, &c., constitutes the establishment. In front of these is the office, a two-story building, the second floor being Edison's private office and library. I glanced over the books on the shelves, and found them to be works on electricity in all languages—probably 500 volumes or more, and some of them very costly. In this office Edison very frequently sleeps on a lounge instead of going home to bed. He was asleep here when we arrived, at half-past eleven Saturday morning, having worked all night and laid down to rest in his clothes after reading the morning papers from New York. When we returned to his office in the afternoon, a servant was clearing away the remains of his lunch, eaten between the calls of visitors. He was kept very busy during the afternoon between visitors and the superintendence of work on his new generator, then being put together, and when in the evening he took us to his home to show the electric light there, his wife remarked that she had not seen him since the morning before, and yet, during all that time, he had not been more than a stone's throw away from home. He is quite as careless of his personal appearance and of his diet as he has been reported to be, but wins and keeps the respect of every man whom he meets by his marked good humor, his earnestness and

59

his keen good sense. When he is listening to any one his partial deafness increases the naturally thoughtful appearance of his strongly-marked face, and he then looks much older than he is. But when he smiles, as he does very frequently, for he is fond of fun, his cleanly-shaven face looks like that of a boy. He is wonderfully well informed, and answers a question involving formulae and mental calculations instantly and with great clearness, provided it relates to anything electrical.

His thirty-five or more workmen and especially his assistants, who are brought into closer relationship with him, are evidently fond of him personally and standing in his workshop directing or talking to either men or boys he appears like one of them. His carelessness as to appearance extends into his workshop, where there is evidently little attention paid to outward looks. A splendid binocular telescope, worth several hundred dollars, standing on a window ledge, had its lenses in good condition, but the polished brass surfaces had disappeared.

The habits of the master in respect to working hours rule many of the men. Nearly all the work is done at night, and at midnight hot suppers are served in the second story of the laboratory building. Here there is an organ, with other musical instruments, a rifle gallery, &c., with which the men can while away an hour or more at midnight rest. So many strangers visit Menlo Park that it has been found necessary to establish a restaurant, which does a flourishing business with reporters and others.

Mr. Edison's chief assistant, Mr. Batchelor, is a mechanic of great ability, who has done most excellent work in carrying on experiments and perfecting inventions. Mr. Upton is the mathematician, who makes all the theoretical calculations, and ascertains by formulas and electrical laws the "reason why" of failures and successes. All work together harmoniously, and Mr. Edison does not fail to give praise and substantial interest in his inventions to those who aid him.

Immense sums of money are expended for experiments alone, much of the material required being very costly. The pay roll of the workmen now amounts to about $800 per week. In the workshops, however, a few of the men are employed exclusively in making Edison's chemical telephone, some of them on an order from the London Times office.

The workshops and laboratory at Menlo Park appear to be entirely open now to the public, Mr. Edison having extended a general invitation to any scientist, who desires to make an investigation of his lamps and generating apparatus, to come to Menlo Park and examine for himself. The electric light cannot, therefore, be classed with such inventions as the Keely motor.

ON FLAMES AND THE VOLTAIC

Eng Mechanic Dec 12/1879

THE thermal absorbent and emissive power of flames and the temperature of the voltaic arc have been recently a subject of numerous experiments by M. Rosetti. His conclusions are given in a letter to M. Cornu, and are as follows:—

1. The transparence of flames is very great: hence they exert very small absorption on thermal radiations which traverse them. If the radiation be from a flame of the same nature, and if the flame traversed have a thickness of 0·01m., the co-efficients of transparence and absorption are represented respectively by the numbers 0·865 and 0·135, and this is in the case of white flames of ordinary lighting gas and the pale blue flame of Bunsen burners.

2. The transparence diminishes and the absorption increases proportionally if the thickness of the flames be increased. If a flame be of infinite thickness it is athermanous; that is, it absorbs all the thermal rays coming from a flame of the same nature; the transparence is *nil*, the absorption equal to unity. These limits are, however, nearly attained with finite thicknesses, which are not very great either. One metre of thickness already suffices to render a flame almost completely athermanous for rays from another flame of the same nature.

3. The formula $y = a\,\dfrac{1 - k^{\epsilon}}{-\log hk}$ represents very well the intensity of the thermal radiation emitted by flames of any thickness ϵ, the co-efficient of transparence being $k = 0{\cdot}865$, the thickness ϵ being expressed in centimetres, and a being a constant quantity, the value of which depends on the nature of the flame.

4. The absolute thermal emissive power of *white* flames produced by ordinary lighting gas (that is to say, the intensity of radiation of a flame of this nature having an infinite thickness compared with the intensity of radiation emitted by soot at a temperature equal to the mean temperature of the flame) is equal to *unity*. The absolute thermal emissive power of the *pale blue* flames of Bunsen burners is represented by the fraction 0·3219, that is to say, it is nearly the *third* of the emissive power of white flames of coal-gas.

5. The *relative* emissive power of a flame of given thickness may be obtained by multiplying the ratio between the intensity of its radiation and the *maximum* intensity (intensity of radiation of the same flame if its thickness were infinite) by the number which represents the absolute thermal emissive power of this kind of flame. A pale blue Bunsen flame of 0·004m. thickness has its thermal emissive power expressed by the number 0·0177, that is to say, that soot raised to the same temperature gives a thermal radiation the intensity of which is $\frac{1}{0{\cdot}0177} = 57{\cdot}73$ with reference to that of the flame.

6. The electric light comprises, it is known, two kinds of radiations, viz., rays emitted by the incandescent carbon, and rays emitted by the voltaic arc between the carbons. The former give a white light, the latter a blue-purple light; the resultant light is bluish white.

7. The two polar extremities of the carbons have temperatures very different. The number of degrees which expresses their temperature may be deduced from the formula $y = m\,T^{2}\,(T - \theta) - (T - \theta)$, supposing the carbons have the *maximum* emissive power.

8. The voltaic arc has a very small thermal emissive power comparable to the emissive power of the pale blue flame of the Bunsen burners. The temperature of the voltaic arc may also be obtained by means of the preceding formula, if there be introduced into this the value of the thermal emissive power of the voltaic arc relative to its thickness.

9. A large number of experiments have given, for the positive polar extremity of the carbon, the *maximum* temperature of about 3900° C; for the negative polar extremity, the temperature of about 3150° C. For the voltaic arc between these extremities the temperature has always been found about 4800°, whatever the thickness of the arc and the intensity of the current.

EDISON'S C[ATS]

Cumming's Bulletin
Phila
Jan 7 1880

The world has learned to have a great deal of faith in Edison. He may not always succeed in reaching the ends he aims at, but he has succeeded in doing some things which seemed preposterous when they were proposed; and when he says he is going to do a certain thing everybody believes him. That is, everybody but the scientists. The quality in which scientists are lacking is faith. As soon as Edison invents anything and puts it into practical operation the scientists invariably come forward wi[th] ma[the]matical, chemical and philosophical demonstrations that that particular contrivance is a practical impossibility. The demonstrations are always lucid and conclusive; and they would be convincing if Edison did not persist, in a peculiarly offensive manner, in permitting the invention to do its work regularly and effectively just as if there were no argumentative scient[ists] anywhere about. We have no doubt at all that he will behave in precisely the same manner when his new machine for the utilization of cats is fully developed and placed in operation. This promises to be one of the greatest of the many boons that he has conferred on mankind. The field in which he has been exploring has been examined many times before. More than one other fruitful and ingenious mind has attempted to solve the problem of the profitable employment of cats; but nothing has been achieved beyond the occasional construction of veal pies and the use of the fur for the manufacture of Siberian squirrel muffs. Mr. Edison, in investigating the matter, not unnaturally had his attention directed to the cat as in a certain sense a source of electrical power; his mind reverting to the days of his childhood when he produced brilliant electrical coruscations from the spinal column of the household cat by a simple process of friction. The thought occurred to him that this electrical element in the cat might possibly be adapted and controlled in some manner to the benefit of man.

While he was perfecting his electric light, therefore, he concluded to try to ascertain whether the introduction of a cat into the circuit would in any manner contribute to the luminosity of the effulgence, if we may be allowed to strain after an expression. Accordingly Edison procured a cat of unusual size and ferocity and affixed the wires to it, using as electrodes one of its fore paws and one of its hind paws. Then he turned on the current. The rumor wh[ich] r[an] w[i]ld about Menlo Park for a day or two afterwards, that a murder had been committed, when traced to its source proved to have been merely the result of a wild wail of anguish which was heard by the people o[f] the place at the instant the circuit was completed. The cat was endeavoring to express its views of Edison's proceeding. But Edison had his eye upon the light and he was overjoyed to observe that whereas it used to have a power of one hundred and twenty candles, the presence of the cat had intensified it to a power of one hundred and seventy candles and nine students' lamps. Stimulated by the success of this experiment, he procured seven other cats and strung them together with copper wire. When the current was turned on the people of Menlo Park fancied with the thought that a tragedy of a bloody nature was being enacted, rushed out with shotguns. But Edison calmly obs[erved] his carbon horse-shoe in the exhausted receiver and perceived that the power of the light had been increased an incalculable number of times. While he was explaining to a friend that the power could be accurately calculated and defined by multiplying the distance by the square of the cats, or the cats by the square of the distance, or in some such manner, he inadvertently laid his hand upon the back of the largest cat. Instantly the light was extinguished, Edison's hand was badly injured and the cats, breaking from the circuit, fled through the windows.

There is an uncertainty as to whether the laceration of his hand was caused by an electrical discha[rg]e or by the claws of an infuriated animal; but the question of the utilization of cats was solved. Give Archimedes a fulcrum and he would move the world. Give Edison cats enough and he will reduce the Sun to a spot of blackness in the sky. And so, unless the Woman's Branch of the Society for the Protection of Animals from the Cruelty of Inhuman Persons who subject them to Torture under Pretense of making Scientific Investigation and of enlarging the general Sphere of Human Knowledge, shall interfere, there can be little doubt that, sooner or later, the harmless necessary cat, in every household, will soon be wired up, when the gloaming comes, and compelled to supply illumination to the family circle. This is Edison's last, best gift to man. The cat, instead of spending its evenings lawlessly and vociferously, poised upon the summit of the midnight fence, will beam lustrously in the sitting-room, flood the h[a]ll with radiance and make the dismal recesses of the kitchen bright with a noonday glory. Edison, no doubt, is the most extra[ordinary] man now on earth.

Engineering Journal

ELPHINSTONE AND VINCENT'S DYNAMO-ELECTRIC MACHINE.

Dec 1 1879

61

THE object of this invention is to obtain electric currents with a less expenditure of motive force than has hitherto been required in working

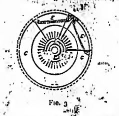

FIG. 3

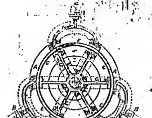

FIG. 1.

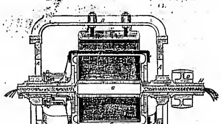

FIG. 2.

dynamo-electric and magneto-electric machines. To this end an arrangement of rotating coils is employed, so applied as to cut the lines of magnetic force, and thereby induce in the coils powerful currents of electricity, which may be used as intensity or as quantity currents.

Fig. 1 is a transverse vertical sectional view; and Fig. 2, a longitudinal vertical section taken through the centre of the machine. In these Figs., A, A, are two standards connected together by the bridges B, B, B, so as to form the framing of the machine. Mounted in bearings in the standards A, A, is a hollow drum C, made of brass or some other non-magnetic material, and provided with hollow journals c, c, which project from the closed ends of the drum. Upon one of these journals, and external of the framing, is keyed a driving pulley D. On the outer periphery of this drum any suitable number of coils of insulated copper wire E, E, is placed.

The method of laying the coils will be better understood by referring to Fig. 3, which represents an end view of the drum and commutator detached, and with two coils placed on it. The wires forming these coils are laid parallel with the axis of the drum from end to end, and over the ends or heads of it, E representing the end of one coil, and E¹ the end of another coil, the free ends of each coil being connected with a commutator F.

By this mode of forming the armature coils, a large proportion of the wire is rendered efficient, and the amount of useless internal resistance is consequently reduced.

Mounted upon a dead shaft G, which passes through the hollow journals of the drum C, is an electro-magnet G¹. This magnet is formed of pairs of radial plates of soft iron, which stand out from the central axis, and are each wound around with insulated copper wire from end to end, as shown in the Fig., and in such a manner as to ensure that upon the passage of a current of electricity through the wire, their outer extremities will become alternately of north and south polarity, as indicated by the letters N and S (which mode of winding is well understood by electricians). The terminals of these wires are brought out through grooves or holes formed longitudinally through or upon the ends of the shaft G, which is kept from rotating with the drum C by means of the bridge piece H, to which it is secured by set screws or otherwise.

Outside the drum C, and in close proximity to it, are placed three electro-magnets I, I, I. These magnets are secured to the bridge O, B, of the main frame by the bolts and nuts b b, by which they can be adjusted, and they are so placed with respect to the radial plates of the magnet G¹ that their poles are opposed to the poles of the magnet G¹.

The magnets I, I, I, are wound with insulated wire in such a direction that upon the passage of the current their poles will be in opposition to the poles of the magnet G¹, as indicated by the letters N, S. The commutator F is formed of thin plates of metal placed radially around the hollow journal of the drum C, and insulated from each other and from the journal by vulcanite or other suitable material. The brushes for collecting the induced currents are carried by a ring K, secured to the main frame of the machine, but insulated from it; they do not possess any special feature above those ordinarily employed for such purposes.

62

The Times
Sat Jany 10th 1880

THE WONDERS OF LIGHT.—Last night Mr. W. H. Preece, Electrician to the General Post Office, followed up the former of his two lectures to young people, under the auspices of the Society of Arts, which was on "Recent Wonders of Sound," by the second, entitled "Recent Wonders of Light." Lord Alfred Churchill, Chairman of the Council, presided. Mr. Preece began by pointing out the analogies and differences between sound and light. Like sound, light varied in pitch, intensity, and quality. But the velocity of light, no less than 180,000 miles a second, was inconceivably greater than that of sound, which was but 1,100ft. in the same space of time. Again, while the length of a sound wave produced by the voice varies between one foot and 17ft., that of light varies between the thirty-[illegible]-thousandth and the sixty-thousandth part of an inch. The fewest vibrations the ear is struck by at once are but 16, the lowest number received by the eye is 500 millions of millions. The composition and decomposition of light were illustrated by the [illegible] experiments. The softest light was that due to phosphorescence, seen sometimes in the sea as well as in fireflies and glow-worms. This was caused by sheer vibration set up in certain bodies by light itself, and was well exemplified by the new luminous paint. A surface covered with this paint needed but an instant's exposure to the action of light to become permanently phosphorescent. This invention might be utilised for life-buoys at night; to enable us to find our Bryant and May in the dark; and, as the experiment of "the writing on the wall" showed, for making the names of streets legible without the help of gas. In speaking of the uses of light, Mr. Preece sketched slightly the history of illumination from the days when savages first struck out sparks and flame by friction till men learnt to burn oil, wax, and tallow—nay, until they used for the purposes of illumination gas and electricity. London was first lighted by oil lamps in the reign of Charles II. (1684); gas was first employed for the purpose in 1813; electricity on the Thames Embankment and Holborn Viaduct not before last year. The constantly accelerated improvement in burners and in the plant and processes employed in the manufacture and distribution of gas in modern times was profusely exemplified. The only experiment which signally broke down was that so common among boys—the distillation of coal in the bowl of a tobacco-pipe.—The youngsters, of course, laughed heartily at the failure. Mr. Preece remarked that in nothing are householders so neglectful as in regulating the supply of gas to their dwellings. The great increase in cost last year was due to a necessarily increased pressure at the works, which ought to have been, but was not, compensated for at home. The waste of gas, and consequent loss of light, were fabulous, owing to the absence of any means to regulate the consumption at the burner. Gas burning 5ft. per hour should give 15-candle light. As was proved by experiment, flame implied something to burn and something to burn it with. The pale light from the spirit lamp became immeasurably brighter when Mr. Preece fed it with fuel blown from a tube. The combustion of carbon in oxygen and of magnesium wire in common air, with other like experiments, illustrated the nature of flame, and the inseparable connexion between motion, light, and heat. In fact, heat and light were identical, and the greater the heat, the greater the light. The solution of the problem of the best illuminant depended on our being able to concentrate the greatest heat on the smallest particles of matter. This was best effected by electric currents. The mightiest currents were produced by moving coils of wire with the greatest velocity through the strongest magnetic field. The light produced varied with the strength of the current. The various systems for producing the electric light were then briefly reviewed and illustrated experimentally. At a given instant, four lamps in the theatre and one on the stairs were lighted up with electricity pumped up by the Embankment works at Charing-cross. The lecturer ridiculed the latest news of Edison's asserted triumphs. The Menlo-park achievement of obtaining 128-candle light from a single horse-power had been already exceeded tenfold on the Siemens system.

63

Manufacturer & Builder

Light and Heat.

Dec. 1879

Our attention was attracted by the above title in an article by Henry Raymond Rogers, M.D., of Dunkirk, N. Y., first published in the Buffalo *Sunday Courier*, and reprinted in the *Journal of the Telegraph*. A country paper, not claiming to be scientific, might be pardoned for inserting the article referred to, written by a man who, in almost every sentence, proves that he knows very little of the subject he treats, and who makes several statements contrary to what science has demonstrated; but that a journal published in the metropolis of the American continent, and claiming to be scientific, should have no one on its editorial staff who is enough of a scientist to see the utter worthlessness of the whole article in question, and publishes all its nonsensical utterances without comment, is a disgrace to the scientific reputation of the United States, while at the same time much harm is done by the diffusion of erroneous theories and of statements which are utterly untrue.

We feel ourselves called upon to correct the theories and statements referred to. The writer begins by reproaching scientists for having thus far ignored the two forms of light and heat, which he holds to be combustion and magnetism. By the latter he means the light and heat produced by electric currents, which do not appear at the seat where they are generated, like the light and heat of combustion, but, as the writer expresses himself, "this magnetic force, while permitted to flow freely through a perfect conductor, is never developed into light and heat, but is only converted into these forces as the current encounters and overcomes resistances." He further says: "They are transmissible in any direction, and by any pathway, and have scarcely any terrestrial limits. They are transported by wires over continents and beneath oceans, and many miles of space have been traversed by them without any visible means of conduction; but, unlike the former, they do not pass as sensible light and heat. Their functions differ; the light of combustion is feeble in power, while the magnetic form of light may be employed in photography, and by it the various shades of color may be discerned in the night season. In strength and brilliancy the magnetic light resembles the sunlight."

The writer, when he states that the light and heat of combustion do not appear at the seat where they are generated, forgets the works in which gas is generated, while the light and heat which it contains in a latent condition are often evolved miles away from the place of generation. In fact, we now know that there is far less loss in transmitting light and heat in the form of gas than there is in transmitting them in the form of electricity, which do not at all "flow so freely," and have decidedly a very contracted "terrestrial limit," as those who professionally exhibit electric lights have learned to their great annoyance. To say that electricity can traverse space "without any visible means of conduction," is downright nonsense.

It also appears that the writer desperately confounds electric currents and magnetic force, which are by no means the same thing, however closely they may be related. He persists in calling the electric light "magnetic light," while it is well known that it can be, and was at first, exclusively produced by simple galvanic batteries, without the aid of any magnetism; and that only at a later date, after it was found that magnetism could produce electric currents, were magneto-electric machines used to develop electric currents. To say that it is magnetic force that flows through conductors displays as much ignorance as when he says that the light of combustion is feeble in power, while the "magnetic form of light may be employed in photography." The fact is that the light of combustion may be made as strong and as well suited to photography as the electric light, the combustion of magnesium metal, of bisulphid of carbon with nitrogen, of phosphorus in oxygen, or of oxygen gas blown upon burning sulphur, which are all adapted for photography, while only a strong electric light will answer the purpose. It is not a question of the origin of the light, but of its temperature.

The writer wants to deduce the conclusion that the sun shines by "magnetic light," and tries to obtain another argument from the fact that by the "magnetic light colors can be distinguished." Unfortunately for his theory, the light of burning magnesium shows colors just as well as the electric light; so does the light produced by the ignition of many other substances, if it is only pure white light, and not yellow, like that given by our ordinary gas, lamp and candle lights. He thinks it "a great relief" to suppose that the solar light is magnetic, as then he says "we are eased of the great burden of finding adequate supplies of material to keep up the vast conflagration supposed to rage at the sun;" and then expounds in regard to the tax of the old theory upon the ingenuity which "neither we nor our scientific fathers have been able to bear." He says that if we only adopt his magnetic theory, the trouble about the "waste involved in the theory of combustion process, enormous beyond computation," will all be relieved, and the great law of the conservation of force, which was jeopardized, be maintained.

Does Dr. Rogers then think that he gets his magnetic (electric) light for nothing? Does he forget that for its production he needs a colossal galvanic battery consuming zinc and acids by the pound? or that he wants a steam engine to drive the dynamo-electric machine producing the light? so that in the end he needs a combustible material as much as if he made a fire and used its more diluted heat and light directly, without the intervention of electric currents; and we ask him: Where is the galvanic battery or the dynamo-electric machine, with the power driving it, which supplies the solar magnetic (electric) light? It is easy enough to pretend that the source of solar light and heat is electric or magnetic if you choose, but this explains nothing if no further explanation is added in regard to how the electricity is generated.

We pass by some other confused notions expressed by Dr. Rogers, and will only mention the analogy he finds between the attraction of our little magnetic batteries and the attraction or gravity of the great sun battery, as he calls it, and which attraction, he says, "is likewise an integral constituent with sunlight and sun heat." Unfortunately for such speculation is the well proved fact that gravitation is entirely independent of heat and light.

But the worst is yet to come. In his eagerness to

The Great Discoveries of Edison and Blessings Conferred by the Laws of Nature, and Utilizing Them for the Benefit of the Human Race.

Daily Gazette

Edison is widely celebrated for the advantages secured to mankind by his remarkable discoveries. He has found the means for utilizing electricity to [illegible] years ago, and when the grand result of his [illegible] tions is summed up it strikes the [illegible] with amazement.

The brilliancy and utility of his achievements are undeniable. Nobody questions them. [illegible] ready to accord them due commendation and encouragement. If he does nothing beyond what he has already accomplished, the measure of his fame will be as complete as that of any scientist of the nineteenth century. And yet there are others who deserve well of mankind—who have conferred inestimable benefits upon the world by their [illegible] discovery.

[illegible]

In the various attacks against butterine which have been made from time to time, the people of this city are surprised to see that they are aimed at an industry [illegible]

[illegible]

So grand a discovery as Edison's is not grasped by the ordinary mind [illegible]

[illegible] in individual and concerted action they [illegible] to State legislation, securing by mis[illegible] and falsehood the enactment and [illegible] of laws that are a disgrace to the statute [illegible] should be condemned and repudiated by intelligent people. His discovery has [illegible] vast industry, employing thousands of people, large capital, which have added not only [illegible] wealth of this land, but to the commerce of [illegible] world. And so we predict the scientific researches and struggles of Edison will be equally grand, and as far reaching in practical results to the masses of mankind.

EDISON'S ELECTRIC LIGHT—EFFECT ON GAS.

Chicago [illegible] Dec 29 1879

The latest intelligence from Menlo Park confirms the first announcement of the [illegible]ness of Mr. Edison's electric lamps, notwithstanding the persistent declarations of his critics and cavilers that they would not succeed. Mr. Sawyer, the self-claimed New York electrician, has affirmed in a testy and confident manner that the little carbon horseshoes would not burn an *hour*, but in Edison's laboratory they have been burning a *week*, and there is apparently no reason why they should not burn for an unlimited time.

A French electrician in New York has declared with equal vehemence that Edison could not make a perfect vacuum in his globes, since the air would creep in at the point where the wires enter from the battery to the horseshoe; and the moment that oxygen entered the carbon would crumble and the light would instantly be extinguished. Edison has shown, however, that the carbon continues to give forth light, and consequently that the vacuum is perfect. To their confident declaration, "You cannot do it," he can answer, "I have done it," much as the woman confounded the lawyer who assured her that her husband could not be put in jail with the declaration that he *was* in jail. Against their theories he opposes the accomplished fact, and the world is already congratulating the skillful young electrician upon his marvelous and brilliant success.

One of the foundation elements of that success may not be completely understood by our readers, and that is, how the light is produced. The horseshoe is made of carbonized pasteboard, inclosed in a small hermetically-sealed globe, from the prongs of which platinum wires, also in the vacuum, connect with copper wires outside the lamp, these in turn uniting with iron or steel wires leading to the battery. The electricity traverses the latter wires with the usual velocity, amounting to many thousand miles a second. They are so perfect conductors that the resistance is not appreciable. The platinum wires, on the other hand, are poor conductors. They probably give [illegible] and [illegible] more resistance than iron or copper; while the carbon is so poor a conductor that the electric current can hardly creep around the horseshoe. The progress of the current in making its circuit may be compared to a skater flying at great speed over very smooth ice, who suddenly strikes upon a bit of bare ground. His speed is at once so retarded that he only goes a foot or two and strikes fire at the same moment. To appreciate the influence of the carbon upon the current, suppose that this same skater were to suddenly, at his moment of swiftest speed, strike upon a surface of sandstone. He is not only instantly stopped, but much heat and flashes of flame are generated by the frictional contact, and bright sparks fly thick and fast under his foot. So with the electricity. Flying with inconceivable rapidity and force over the iron and copper, it suddenly encounters the non-conducting platinum and the tremendous resistance of the carbon. Force, when met with resistance, always converted into heat, and, if the motion is great and the resistance is strong enough, into light. If it encountered the platinum alone, heat would be generated sufficient to fuse the metal, as Edison found in his earlier experiments; but, with the carbon, whose non-conducting resistance and infusibility are still greater, it not only [illegible] heat, but light of a beautiful, mellow [illegible] at the same time brilliant, radiance. [illegible] has ascertained that fully nine-tenths of the velocity force of the electric current is converted into light, and but one-tenth into heat, upon striking the carbon burner. Whereas, in the combustion of gas fully nine-tenths thereof is given out in the form of heat and only one-tenth in light. And this is why electric force can be converted into light cheaper than gas can; but for heating purposes gas would be at least ten times better and more economical than electricity.

One of the most frequent opinions expressed since Mr. Edison's discovery is to the effect that it will result in excluding gas from use and entail total loss upon the holders of gas property. There is little danger of this. Before kerosene came into very general use, gas was charged in Chicago at $4 and $4.50 per 1,000 feet. The oil cut down prices to $2.50 and $3, but there was no complaint on the part of the gas companies of any considerable loss of profits, nor did their stock materially suffer. Suppose that Edison's discovery should still further force down price of gas to $1, or $1.25, or even 75 cents per 1,000 feet, there would even then be no danger of annihilation of the gas business. The profits on gas hitherto have been so enormous that the stocks and "plants" of companies were long ago paid for and the investment capital returned to the subscribers several times over in nearly all the gas companies in this country and Europe. If hereafter gas should be sold so cheap as only to reimburse material, labor, and repairs, with 8 or 10 per cent thereon for superintendence, the business would go on, and no gas company wind up and abandon the business; and probably the much profit could be made on gas at 60 or 75 cents per 1,000 feet. Gas is available not only for illumination, but for heating. We have already stated that nine-tenths of its product is heat. If the price is forced down by the electric light to one-third even of present prices, the effect will be to create an enormous demand for gas for heating purposes. It will then come into universal use in domestic economy as a heater. The gas companies are already considering this question, and contemplating the enlargement of their works for the manufacture of the vastly increased amount which will be used in stoves, grates, and in various other ways where the electric light can be of no avail. There is no danger that any one will warm himself by lightning, or cook by it. Gas will be cheaper than any other fuel, will cook better, will save on the purchase of coal and wood, will do away with smoke, dust, soot, and dirt, can be lit instantly, and shut off as fast. While, therefore, Mr. Edison's invention may be a great blessing to the world in the way of better and cheaper illumination, there is no reason for holders of gas stocks to get in a panic. Gas has too many and too valuable uses to be shut out even by the lightning.

ELECTRICITY AND GAS.

THE NEW INVENTION AND THE OLD.

Dec 30 1879

How Gas Had to Fight Its Way—Electric Street Lamps To-Night.

"SCEPTICS DIE HARD."

MENLO PARK, Dec. 29, 1879.

It was quiet out here this morning and through the day as far as visitors were concerned. The machine shops were running full blast, and the laboratory was endued with its mysterious activity to the full. You would get the idea at first that in this place work was only taken up spasmodically, because you might see a man in broad daylight asleep on a bench, but shortly you discover that they only leave off work for short spells. Hence a peculiar Bohemian air about the place and all who are in it that might be a sign of demoralization in any other establishment in the world. Of this more anon.

VISITORS COMING.

The afternoon trains brought some visitors, but in the evening every train set down a couple of score at least. All immediately started for the scene of the laboratory, and a good many of those simple people who hold that Rome was built in a day and those modest people who believe that the hinges of the universe should turn upon the pivot of their desires expressed disappointment that they did not step out of the train upon a scene from fairyland. The moon was obscured by clouds, the way was dark up the little plank road, and the new white lamp-posts seemed to be stretching up their long fingers to clutch a little light from the heavens when Edison would not give them any of his little horseshoes. In fact, as the inventor said to me to-day, he is only waiting for another electric generator to be finished to light up all those long white fellows in what is out of courtesy called a street. It will, he expects, be ready to-day, and to-night he hopes to have fifteen street lamps and several of the houses lighted up.

[illegible] NO POWER.

"It is a mistake to [illegible]," said Edison, "that a [illegible] here or [illegible] Menlo Park is all I [illegible] to make [illegible] of my eighty [illegible] engine and to put every lamp it will [illegible] to have 800 of them [illegible] I'll put a dozen of them over there a table away [illegible] turn them on and off from this window. I don't know where I'll put them all, unless along the [illegible] everybody will have plenty of time to see [illegible] it will take weeks to get them all out, though [illegible] are working night and day."

THE ELECTRIC REGISTER.

The stream of visitors passed through the shops, [illegible] wondered at the steady electric lights [illegible] by all sorts of laudatory epithets. [illegible] a well informed visitor would catch [illegible] or Mr. Upton and ply him [illegible] upon candle power, gas jet [illegible] kindred intricate matters that [illegible] to the general." A particular object of interest was the register for regulating the strength of the current. Young Francis Jehl stood by it with all the solemnity of a patriarch, and explained it lucidly to all who desired. A current passing through a galvanometer deflects a small mirror at the back of which is a tiny magnet. Opposite this mirror, at a couple of feet distance, is a board along which, horizontally laid, is a scale. Through a slit in this board a ray of light passes from a lamp. The ray falls upon the small mirror, which, as the current is stronger or weaker, casts the reflection to the right or left upon the scale opposite. As more lights are put on more electricity is needed, and Francis turns an indicator, near which is an electric light, just as they do in a gas house when more or less pressure is called for by the consumption.

"It may be done automatically," said Mr. Batchelor, in answer to a gentleman's inquiry; "but it hasn't been thought out yet."

AN AGED SCEPTIC.

The visitors seemed never tired of lighting the lamps upon the main table, by simply laying one between the two long wires. Most were content to ejaculate "Wonderful!" But no amount of explanation would persuade one old gentleman that it was not an iron wire that was inside the glass globe. It could not be the carbon filament of a piece of paper, for, said he, "I have seen red hot, white hot iron wire, only it was not quite so bright, but it looked just like that. That's no flilymeut."

"This is a bad time for sceptics," I said to Edison.

"There are some left," he said, "they die harder than a cat or a snake."

I turned away reflecting how snakes will bite in dying, and thought the inventor had described the persistent scientific doubter of demonstrated facts pretty accurately.

THE STRUGGLE OF GAS.

It reminded me of the sceptics at the time coal gas was first applied to illuminating purposes. There is, of course, a great change in the attitude of the masses to inventions nowadays. So much has modern science accomplished that people in general are rather inclined to be credulous than sceptical in matters of invention. At the beginning of this century it was very different. The alchemists—the searchers for the philosopher's stone that was to transmute brass to gold—were regarded as having been vain dreamers or impostors, and those searching amid the products of nature for fresh knowledge were looked on as their direct successors. It is close to two hundred years since the Rev. Dr. John Clayton, Dean of Kildare, wrote to his friend, Edward Boyle, a letter which was not published, however, until 1739, giving an account of his strange discovery. He was an experimenter, and he tells how on distilling coal in a retort on an open fire "at first there came over only phlegm, afterward a black oil and then likewise a spirit arose which I could no ways condense; but it forced my lute or broke my glasses. Once when it had forced my lute, coming close thereto, in order to try to repair it, I observed that the spirit which issued from it caught fire at the flame of the candle, and continued burning with violence as it issued out in a stream, which I blew out and lighted again alternately for several times." Then he filled a bladder "void of air" with this "spirit." He endeavored to condense it several ways, but in vain. "And when I had a mind to divert strangers or friends I have frequently taken one of these bladders and, pricking a hole therein with a pin, and compressing gently the bladder near the flame of a candle till it once took fire, and it would then continue flaming till all the spirit was compressed out of the bladder, which, he naively adds, was more surprising because no one could discern any difference in the appearance between these bladders and those which are filled with common air."

MURDOCH'S ILLUMINATION.

Yet close to a century elapsed from the time of Kildare's writing and over fifty years from the publication of his experiments before any practical steps were taken in using coal gas for illumination. In 1792 Mr. Murdoch, a Scotchman, first tried it in Cornwall and afterward in 1798 established an apparatus on a more extended scale in a Birmingham foundry, the Soho Works. There were then no swarms of hungry professors and "practical" men going about trying to steal other men's brains in applied science, and Murdoch worked on without attracting great attention. But an opportunity at last presented itself for a public exhibition of gas illumination. On the conclusion of the peace of Amiens the people of England were rejoiced indeed. The Jingoism of the British nation had cooled for the moment, and when it was known that the treaty of peace was all but signed preparations were made all over the kingdom for "lighting up." The illuminations were general, and we read how a mob of the Jingoes of the period assembled before the French Minister's house, and not finding the blazing device quite to their taste made him change it. The word "Concord," it appears, offended them, as that was the way the majority of them spelled "conquered," so the obliging Ambassador changed it to "amity." Then, seeing the letters "G. R." without a crown, they thought it was a republican slur upon His Majesty King George III. of insane memory, so the French Minister, ever willing to oblige *ses amis l'ennemi*, got out a blazing crown. But all these illuminations were in oil and candles save in one place, and that was the exterior of the Soho Works in Birmingham.

1802-1879.

When we see the people walking about at Menlo Park admiring the electric light of Edison we may well recall in 1879 the scene at Birmingham on the night of the 28th of January, 1802. Says Matthews, describing it:—"The illumination was one of extraordinary splendor. The whole front of that extensive range of buildings was ornamented with a great variety of devices that admirably displayed many of the varied forms of which gaslight is susceptible. This luminous spectacle was novel as it was astonishing, and Birmingham poured forth its numerous population to gaze at and admire this wonderful display of the combined effects of science and art. The writer was one among those who had the gratification of witnessing this first splendid public exhibition of gas illumination and retains a vivid recollection of the admiration it produced."

A BATTLE WITH IGNORANCE.

Still gas had not then won its decisive victory, although the demonstration was perfect. We trace it along through the succeeding years struggling with ignorant prejudice, perverted humor and cheap satire. In 1805 it was introduced into a cotton mill at Manchester. Nearly one thousand burners of different forms were employed, and we are informed by Mr. Murdoch that "the peculiar softness and clearness of the light, with its almost unvarying intensity, brought it into great favor with the workpeople, and its being free from the inconvenience of sparks and the frequent necessity of snuffing, are circumstances of material importance, as tending to diminish the hazard from fire, to which cotton mills are so much exposed."

But although it reached London speedily, and found in Mr. Winsor an enthusiastic promoter, it had to fight its way at every step. The explosive nature of gas mixed with common air became known and frightened many. Then the great train of interest that supplied street lamps—just look at Hogarth's

66

pictures for an illustration—the great tallow interest, the great candle-making interest, the great candlestick interest, the great wic making interest, the great snuffer-making interest, all combined to denounce gas illumination as "wild, absurd and extravagant in its conception and fraught with the greatest danger to the nation." The popular writers in the papers made light of the "preposterous innovation," as Winsor's gaseous proposals for enlightening the inhabitants of London, his "smoke lights" and his "fire of wind" to their hearts' content. Oddly enough nowadays it is from so-called scientists that the loudest opposition comes to the equally demonstrable incandescent electric light. But Winsor fought seventy odd years ago with a wonderful enthusiasm. He attracted the attention, however, of some discerning men of wealth anxious to promote science—and make a little more money. On the 28th January, 1807, the first public street lighting took place in Pall Mall, London, near Mr. Winsor's laboratory, which stood on the present site of the Carlton Club. Subsequently, in 1813, old Westminster Bridge was lighted with gas. Yet it was adopted generally by very slow degrees.

SLOW SPREAD OF THE GAS MAINS.

In 1821 a Thames fisherman, arrested for using an illegal net, complained that the discharge of gas water into the Thames from the works near the Temple destroyed the fish, and the Lord Mayor sympathized with the poor man and made his fine merely nominal. Still that gas was far from being in general use may be judged by the strenuousness with which we find the advantages of gas over oil and candles insisted on in the London *Encyclopædia* of 1821. "Many persons," it says, "object to introduce the gas directly into their apartments; and it has accordingly been proposed to bring the gas to the window, to allow it to burn on the outside, and thus to illuminate the room without any of the annoyances which arise both from the smell of the gas and from the heat generated during its combustion." Then it gives directions how such a light should be made. "The light might be rendered uniform by means of an ornamental blind of the finest muslin (varnished or not as may be found most advantageous), and if the blind has a landscape upon it the most luminous portion, or that nearest the gas flame, might be made to have the appearance of the sun in the heavens."

THE COMING BATTLE.

All this comes back with renewed force to me when another revolution in domestic illumination is impending. If it is a better, purer, more manageable, cleanlier, and, above all, a cheaper light than gas, then gas is doomed. Of course no revolution like this can take place in a day or a year, but as the gas men crowded the oil men and candle men into a little corner, giving them only the refuse of the lighting of the streets and houses, as coal oil pushed the poor candle men still closer to the wall, so the electric light begins to push all three of these. That is inevitable, though the uses of gas for purposes in which it is now but sparingly used will be studied out with persistence and ingenuity. When we think of the enormous amount of capital invested in gasmaking we can easily guess how mighty the struggle will be.

EDISON'S BRAIN MOTOR.

Up there at the laboratory there is no particle of doubt in any one's mind that the electric light is a success and a permanent one. I spoke yesterday of the enthusiasm of a young glassblower but it is a curious instance of Edison's brain force that this enthusiasm is common to all about the place. It is not unusual in such establishments for the inquirer to find here and there a captious understrapper who with very little encouragement will proceed to belittle their master. I have found nothing of the kind here. Edison animates the men and boys—there is scarcely a gray head in the establishment—with his own indomitable, persistent spirit. It is not merely in talking to a stranger, but in working, that this is seen. Edison's chief assistant, Mr. Batchelor, will glow like a carbon lamp when he is asked a question. Secretary Griffin, who sits up in the office, generates enthusiasm with eighty horse power if you hint at a desire for information, and it is all done with bonhomie and has nothing of "shop talk" about it. Mr. Upton is genial and answers questions with tact

both exactitude, although the object or process may be only a week old. The truth is Edison attracts the right kind of people for his work, and his "go" keeps them going. It is not mere day's work that he exacts from them or himself.

"I want people to do as I tell them just when it suits me," said he. "I don't want any man that's afraid to burn his fingers."

This rather took me aback, so I asked, "Burn his fingers?"

"We had a young gentleman come here from college, with a first rate diploma and all that. He was a chemist. He could answer any questions; but, somehow, he seldom could get anything out. I believe he was afraid to burn his fingers. You mustn't be afraid of your work. I said to him one day, 'I want two ounces of iridium.' He worked and worked, but somehow he didn't get it. We were working here one evening and I wanted it badly next morning, so I said to Batchelor, 'Batch, do you know anything about iridium?' 'Not much,' said Batch. 'Well,' said I, 'go and look it up. I want two ounces in the morning.' Now, Batch is not a chemist, but he went to work all night and in the morning he had four ounces for me. That's the way I want it. I'll tell you more about it some other time."

SALE OF ELECTRIC LIGHT PA[TENTS].

CLEVELAND, Ohio, Dec . 1879.

Charles F. Brush, of Cleveland, has ju[st so]ld his English patents for electric lighting app[aratus] to a large incorporated company in London [for] $30,000.

A SCIENTIFIC VIEW OF IT.

Plumber & Sanitary Engineer Jan 1 1880

[From the New York Times of Dec. 28th.]

Prof. Henry Morton, the President of the Stevens' Institute of Technology, who is well known for his researches in physics, and whose experiments were a source of unfeigned pleasure and astonishment to Prof. Tyndall, recently sent a communication to the SANITARY ENGINEER protesting against the trumpeting of the result of Edison's experiments in electric lighting as a "wonderful success," when "every one acquainted with the subject will recognize it as a "conspicuous failure." To this was added the statement that Edison "has done and is doing too much really good work to have his record defaced and his name discredited in the interests of any stock company or individual financiers" Edison, to whose attention this letter was called, was reported in a newspaper yesterday morning as inviting Prof. Morton or any other electrician to visit the Menlo Park laboratory and see the light in practical operation. In conversation with a *Times* reporter yesterday, Prof. Morton said that, for several reasons, he did not think he would accept Mr. Edison's kind invitation. "What is needed to be learned," said the Professor, "is the durability of these new lamps of Mr. Edison's, and the actual economy in the conversion of power into light by his arrangement. For example, according to the statement in the *Sun*, Mr. Edison places his present lamps and machines as yielding him what is equivalent to 10 gas-burners for every horse-power. Now, my own experience with the best dynamo-electric machines—such as those of Siemens, Weston, Brush and Maxim—using the ordinary carbon poles, show that we may obtain a light of from 1,200 to 1,600 candles per horse power. Assuming a gas-burner to be equal to from 12 to 16 candles, this would be about 100 burners per horse power. As compared, therefore, with the electric light obtained between carbon poles, Mr. Edison gets only 10 per cent., showing, therefore, precisely that enormous loss in the division of the light which has been alluded to before as one of the standing difficulties in the way of the practical application of such a system as Mr. Edison is working upon. This is taking simply his apparently rough estimate. For any definite and certain conclusions, prolonged and careful experiments, entirely under the control of the investigator, are absolutely necessary."

As regards the durability of Prof. Edison's new lamps, Prof. Morton was not at all sanguine. "Lamps," said he, "in all essential respects identical with these described by Mr. Edison, have been in constant experimental use for several years past, with one invariable result, namely, that, while the carbon would operate successfully for periods varying from a few hours to several days, it has been found utterly impossible to render them reliably permanent. It is, therefore, in my estimation, here also necessary that experiments of some length, likewise under the entire control of the investigator, should be made in order that a decisive conclusion may be reached. With reference to the confident assertions of success which reach me from various quarters, I must fall back upon my experience of a little over a year ago. Every one remembers how, at that time, Mr. Edison read some remarks of mine by the light of his then brilliantly-glowing electric light, and pointed to it as a shining refutation. In turning over some old letters a few days since, I came across one from a friend of mine, who is a scientific man of high standing, and was at that time on very intimate terms with Mr. Edison. This letter is dated October, 1878, and in it I am assured that Mr. Edison's lamp is a perfect success, capable of replacing a gas-burner, and that when I see it I shall, no doubt, be charmed with its simplicity and efficiency. When I reflect that this previous complete success has been since abandoned by Mr. Edison, I feel that a little caution is needed in accepting the enthusiastic conclusions of his friends, even when they are illuminated by the shining electric lamps which occasion them."

"Can you tell me, Professor," asked the reporter, "what are some of the chief difficulties in the way of the success of Mr. Edison's light?"

"Well," Prof. Morton replied, "the first difficulty of all is the production of a lamp which shall be thoroughly reliable, and neither complicated or expensive. All attempts up to the present lamp in this direction are acknowledged to be failures, and, as I have pointed out, there does not seem to be any novelty such as would authorize us to hope for a better success in the present one. The next difficulty is in the economical production of small lights by electricity. This is what is commonly meant by the phrase, 'dividing the electric light.' Up to the present time, and including Mr. Edison's latest experiments, it appears that this involves an immense loss of efficiency. Next comes the difficulty of distributing on any large scale the immense electric currents which would be needed, and to provide for their equal action at different points under varying conditions of the number of lights used. In reference to this, as far as I judge from the reports, Mr. Edison has been running not over 50 lights in all, while his 80 horse-power engine ought to supply 800 lights. The small number actually in use does not, therefore, develop this problem in any practical way."

"The question of measuring the current," added the Professor as the reporter turned to leave, "the loss involved from the necessity of running the machinery without a moment's intermission during the entire time that any light is needed—in other words, the absence of any storing capacity in electricity—and various other matters of detail, while less important than the three principal difficulties which I have given you, are, nevertheless, very serious difficulties in the direction of a successful practical application of electricity for general illumination."

67

EDISON'S ELECTRIC LIGHT.

THE REPORT OF AN EXHIBITION AT MENLO PARK UNTRUE.

Date ?
6 Dec '79

For some time a rumor has been circulated that Edison, the famous inventor, intended to illuminate the village of Menlo Park, N. J., with his electric light on Christmas Eve. A director of the Electric Light Company that is supplying Mr. Edison with money to prosecute his undertaking said to a TRIBUNE reporter yesterday:

"The report is untrue; we have made no preparations to illuminate Menlo Park to-night. We never have set a day for making a trial of Mr. Edison's inventions for using the electric light—that idea was the creation of some visionary reporter's brain. The apparatus is not yet perfected, nor has some of it been tried; nor has Mr. Edison, I think, yet obtained his patents for some of it. Many experiments will be made before the directors of the company will feel it inviting the public to an exhibition. The company has already been subjected to a great deal of ridicule in consequence of the publication in the newspapers of exaggerated reports of the results of Mr. Edison's labors, and is not inclined to invite any more by a display of the electrical machines while they are yet imperfect and not thoroughly tested. We do not yet know positively the cost of manufacturing and distributing the electricity. Laboratory experiments cannot be entirely trusted. I doubt if we will know the cost of the electric light supplied by our company compared with the light supplied by the gas companies till the new system can be tested in some large city. Mr. Edison has had poles erected in Menlo Park to hold his electric lamps, and has also put lamps in several houses in the village. The village of Menlo Park is an imaginary one, however, consisting merely of Edison's laboratory, house and two or three other buildings—so that the experiment, when it is made, will not be a very extensive one. None of the directors of the Electric Light Company have been invited to come there to-night to witness any experiments, and I am positive none will be made."

"Was the description, recently given of Mr. Edison's machines and lamps a faithful one?"

"Yes," said the director, "it was faithful as far as it went; but no mention was made of several important inventions inseparably connected with the other parts of the new system of light. I suppose Mr. Edison did not care to mention them, from a belief that others in the inventive world would instantly rush in and say, 'Oh, that's old; we invented that years ago.' But the gas companies evidently have some faith in Edison, for gas stock fell in price in London and Montreal on the publication of the report that Mr. Edison had finally succeeded. The owners of gas stock, I think, are mistaken in assuming that their property will be severely damaged by the introduction of the electric light. The gas companies ought to control the new business, it seems to me, as they have the old. They have the right of way through the streets, the names of customers, in fact the entire business of lighting the cities is in their hands. They can adopt the new method of lighting and still hold the business."

EDISON'S ELECTRIC LIGHT

CONFLICTING STATEMENTS AS TO ITS UTILITY.

THE INVENTOR SAYS HE HAS SUCCEEDED IN GETTING A CHEAP SUBSTITUTE FOR GAS-LIGHT—A PUBLIC EXHIBITION PROMISED—PROF. MORTON'S CRITICISMS.

There was no lack of enthusiasm or of confidence about Mr. Edison as he greeted the TIMES reporter who entered his laboratory at Menlo Park, N. J., yesterday. The inventor, a short, thick-set man, with grimy hands, led the way through his workshop and willingly explained the distinctive features of what he and many others look upon as an apparatus which will soon cause gas-light to be a thing of the past. The lamp which Mr. Edison regards as a crowning triumph is a model of simplicity and economy. In the lamp the light is emitted by a horseshoe of carbonized paper about two and a half inches long and the width of a thread. This horseshoe is in a glass globe, from which the air has been as thoroughly exhausted as science is able to do. So good a vacuum is produced that it is estimated that at the utmost no more than a one-millionth part of the air remains. The operation of pumping lasts one hour and a quarter. At the ends of the carbon horseshoe are two platinum clamps, from which platinum wires run outwardly through a small glass tube contained within a larger one leading out of the glass globe. The small tube contains air. Within it the platinum wires are met by two copper wires connecting with the conductors of the electricity. The air is left in the small tube, because otherwise the copper wires would be fused by the electric current. The carbonized paper is capable of being made incandescent by a current of electricity, and while it allows the current to pass over it, its resistance to the heat is strong enough to protect it from fusing.

The first place visited was the room in which the furnace for carbonizing the paper is situated. The furnace is of the ordinary pattern, and on the coals rested a horseshoe mold, in which the bristol board to be charred was placed. Over each horseshoe a piece of tissue paper was placed, and the whole was washed until all the material of the card-board, except the carbon, was taken away. When the filaments were taken from the mold they resembled pieces of black thread. The particles hung tenaciously together, however, and the black horse-shoe was easily placed in the platinum clamps of the globe of the lamp. The exhausting of the air takes place after the carbon is put in position, and when this is done the lamp is complete. "As there is no oxygen to burn," said Mr. Edison, "you can readily see that this piece of carbon will last an ordinary life time. It has the property of resisting the heat of the current of electricity, while at the same time it becomes incandescent, and gives out one of the most brilliant lights which the world has ever seen. The cost of preparing one of these little horse-shoes of carbon is about 1 cent, and the entire lamp will cost not more than 25 cents." Here the inventor gave a practical illustration of his invention. He was standing just under an ordinary gas chandelier in which two of his lamps were burning. He took one of the lamps out, and it appeared simply as a glass globe. He placed it back in the burner, and immediately a brilliant horse-shoe of golden light illuminated the globe. Mr. Edison then, by turning a screw in the lamp, brought the light down to a spark, turned it off completely, as gas can be turned off, and turned it on again to a brilliant incandescence by a twist of his fingers. He certainly demonstrated that in his own laboratory at Menlo Park, the electric light is as obedient to his will as the gas light is to the general public. The light from each lamp is of about the power of an ordinary gas-jet, but Mr. Edison claims that by increasing the electricity, he can raise the power to 15 gas-jets.

Eighty-four lights are burning night and day in the laboratory, and they are all supplied with electricity by an 80-horse-power engine, which is stationed in the basement of the building. This engine, in addition to feeding these lamps, furnishes the motive power for all the machines in the laboratory, and at night feeds the electric lights which have already been erected in Menlo Park in anticipation of the proposed grand illumination. The wires which are to convey the electricity to the lamps for the grand display are to be above ground, so that all spectators can see and investigate them. They will lead directly from the lamps to the generator in the laboratory, and any person can trace them from point to point.

From the furnace-room Mr. Edison conducted the reporter to the room in which his lamps are made, and where the air is exhausted from them. In this room, also, is Mr. Edison's machine for regulating the pressure of the electricity as it passes to the different lamps throughout his laboratory. This machine consists of a series of coils of copper, over which the electric current is continually passing, and each coil is connected with a series of lamps. If the pressure is too great on any series of lamps it is at once shown by the coil representing that series, and can be regulated in an instant. In this room, also, the carbonized paper is placed in the globes, and the lamp is completed. It is Edison's pet room, and here he spends most of his time when not engaged in studying out new inventions.

It has been asserted by some persons who are supposed to be conversant with the subject of electricity that in order to furnish lights for houses in this City a copper coil as large as an ordinary barrel would be required as a conductor from the central station to the different houses in two or three blocks. Regarding this, Mr. Edison said: "The size and amount of conductors for carrying electricity for lighting purposes depends, of course, upon the distance to which the electricity is to be carried. If I have to carry it 10 miles my conductor must be larger than it must be if I have to carry it 10 feet. My idea is to have central stations to cover, say a district of three or four blocks. The pipes containing the wires on a street, if this idea is carried out, will not exceed in size the circumference of your arm. They will be laid underneath the flagstones just at the edge of the sidewalk, as gas-pipes are now laid."

"What will be the cost of these conductors?" asked the reporter.

"The cost, compared to gas-pipes, will be very small, and there is very little chance of their getting out of order. The wire itself, which will convey the electricity, will be an ordinary No. 9 telegraph wire, the same wire that you see in use every day by the Western Union Company. That is as near the size of a barrel as I intend to get."

"How will the light be distributed?"

"Precisely as gas is now distributed. You see that I can turn that burner off entirely if I wish to; I can lower it or I can raise it, just as you can lower or raise a gas jet. Our electricity will go from our central stations just as gas flows from the meter. Whether the company will charge for the light according to the amount of electricity which each consumer uses, or whether so much a month will be charged to each consumer I cannot say. That is a question which the company will determine when the electric light is introduced."

"Do you intend to illuminate Menlo Park on New Year's Eve?"

"Not for the public as soon as that. Menlo Park is now illuminated every night to a certain extent. All the lamps that we have on hand are lighted nightly, but we cannot give the grand display that I intend to give until we have more lamps. You can say this, however, that the electric light is perfected, and that all the problems which have been puzzling me for the last 18 months have been solved. I expect to have every house here lighted, and a number of street-lamps going within 10 days. When I once get the light started, I shall keep them burning night and day for at least two weeks, in order to make a time test of my carbon. I believe that it is practically infusible, and I have confirmed my belief by experiments here in my laboratory for several weeks, but I want the public to believe it from their own knowledge, and the only way to make the public believe it is to show it to them. I think that my carbonized paper is the only substance which is capable of becoming thoroughly incandescent, and at the same time of offering to the current of electricity sufficient resistance to prevent it from melting away. The vacuum in the globe, of course, offers no oxygen of any consequence to burn; but the intense heat generated by the electricity would destroy any other substance than this carbonized paper. There is absolutely nothing there to fuse. It is carbon, pure and simple, and no machine known to this age can generate enough electricity to destroy it."

"Have any electricians responded to your invitation to see you and investigate your method of lighting by electricity?"

"No electricians have been here yet, nor are there likely to be any here. Electricians are a very scarce article in this country, although there are many persons here who call themselves electricians. They don't come here, because they know that if they do they will be convinced that my light is at last a perfect one. I am glad they don't come. Practical men, with experience, and what I call 'horse sense,' are the best judges of this light, and they are the men whom I like to welcome to my laboratory."

BUSINESS ASPECT OF THE MATTER.

CONFIDENCE OF THE COMPANY WHICH FURNISHES MR. EDISON WITH MEANS.

Mr. Edison's inventions and discoveries, in the way of electric illumination, whatever they may be, are the property of the Edison Electric Light Company, a corporation which supplies him with the money for conducting his experiments. Mr. Calvin Goddard, the Secretary of the company, told a TIMES reporter yesterday that the company had no doubt of Mr. Edison's having perfected his light to such an extent that it can be supplied equal to gas, be as easily managed as gas, and be furnished at a cost not greater than that of gas. The company, he said, was not yet quite ready, mechanically, to show the public the full and complete machinery and the manner of preparing the light, and the statement that a day had already been set apart to exhibit the completed light was incorrect. The first perfect demonstration of the success of the invention will be made at Menlo Park, but just when this will be done cannot yet be told. Time is needed to complete certain necessary fixtures. Among others a large number of lamps are still to be made. The company does not wish to invite the public to inspect the light until everything can be shown, and it is intended to exhibit the full capacity of the 80-horse-power engine to supply electricity to about 700 lamps. The objection which has been raised to the effect that one great difficulty in the way of the success of the light was in the large amount of copper necessary to carry the electricity, had been entirely avoided by Edison, according to Mr. Goddard. The objection was raised in Europe, he said, in the experiments with the Jablochkoff candle, where the cost of the copper was very great. But this difficulty had been overcome, and the company had no fears on that score. When the light is introduced it is intended to generate the electricity by engines of comparatively small horse-power distributed over the City. Each engine will supply the lights for an area of a quarter to a half mile around it, the distance of the engines from each other depending upon the number of lights each has to supply. This arrangement will be made both for the sake of convenience and economy. To be ready for any emergency, as an accident to the generator, duplicate engines will be placed at each of the stations. It is understood that the Electric Light Company does not intend to take charge of the placing of the light, but will simply license others to do so.

A SCIENTIFIC VIEW OF IT.

PROF. HENRY MORTON NOT SANGUINE ABOUT EDISON'S SUCCESS.

Prof. Henry Morton, the President of the Stevens Institute of Technology, who is well known for his researches in physics, and whose experiments were a source of unfeigned pleasure and astonishment to Prof. Tyndall, recently sent a communication to the *Sanitary Engineer* protesting against the trumpeting of the result of Edison's experiments in electric lighting as "a wonderful success," when "every one acquainted with the subject" will recognize it as a "conspicuous failure." To this was added the statement that Edison "has done and is doing too much really good work to have his record defaced and his name discredited in the interests of any stock company or individual financiers." Edison, to whose attention this letter was called, was reported in a newspaper yesterday morning as inviting Prof. Morton or any other electrician to visit the Menlo Park laboratory and see the light in practical operation. In conversation with a TIMES reporter yesterday, Prof. Morton said that, for several reasons, he did not think he would accept Mr. Edison's kind invitation. "What is needed to be learned," said the Professor, "is the durability of these new lamps of Mr. Edison's, and the actual economy in the conversion of power into light by his arrangement. For example, according to the statement in the *Sun*, Mr. Edison places his present lamps and machines as yielding him what is equivalent to 10 gas-burners for every horse-power. Now, my own experiments with the best dynamo-electric machines—such as those of Siemens, Weston, Brush, and Maxim—using the ordinary carbon poles, show that we may obtain a light of from 1,200 to 1,600 candles per horse-power. Assuming a gas-burner to be equal to from 12 to 16 candles, this would be about 100 burners per horse-power. As compared, therefore, with the electric light obtained between carbon poles, Mr. Edison gets only 10 per cent., showing, therefore, precisely that enormous loss in the division of the light which has been alluded to before as one of the standing difficulties in the way of the practical application of such a system as Mr. Edison is working upon. This is taking simply his apparently rough estimate. For any definite and certain conclusions, prolonged and careful experiments, entirely under the control of the investigator, are absolutely necessary."

As regards the durability of Prof. Edison's new lamps, Prof. Morton was not at all sanguine. "Lamps," said he, "in all essential respects identical with those described by Mr. Edison have been in constant experimental use for several years past, with one invariable result, namely, that, while the carbon would operate successfully for periods varying from a few hours to several days, it has been found utterly impossible to render them reliably permanent. It is, therefore, in my estimation, here also necessary that experiments of some length, likewise under the entire control of the investigator, should be made in order that a decisive conclusion may be reached. With reference to the confident assertions of success which reach me from various quarters, I must fall back upon my experience of a little over a year ago. Every one remembers how, at that time, Mr. Edison read some remarks of mine by the light of his then brilliantly-glowing electric light, and pointed to it as a shining refutation. In turning over some old letters a few days since, I came across one from a friend of mine, who is a scientific man of high standing, and was at that time on very intimate terms with Mr. Edison. This letter is dated October, 1878, and in it I am assured that Mr. Edison's lamp is a perfect success, capable of replacing a gas-burner with perfect ease, and that when I see it I shall, no doubt, be charmed with its simplicity and efficiency. When I reflect that this previous complete success has been since abandoned by Mr. Edison, I feel that a little caution is needed in accepting the enthusiastic conclusions of his friends, even when they are illuminated by the shining electric lamps which occasion them."

"Can you tell me, Professor," asked the reporter, "what are some of the chief difficulties in the way of the success of Mr. Edison's light?"

"Well," Prof. Morton replied, "the first difficulty of all is the production of a lamp which shall be thoroughly reliable, and neither complicated nor expensive. All attempts up to the present lamp in this direction are acknowledged to be failures, and, as I have pointed out, there does not seem to be any novelty such as would authorize us to hope for a better success in the present one. The next difficulty is in the economical production of small lights by electricity. This is what is commonly meant by the phrase, 'dividing the electric light.' Up to the present time, and including Mr. Edison's latest experiments, it appears that this involves an immense loss of efficiency. Next comes the difficulty of distributing on any large scale the immense electric currents which would be needed, and to provide for their equal action at different points under varying conditions of the number of lights used. In reference to this, as far as I judge from the reports, Mr. Edison has been running not over 50 lights in all, while his 80 horse-power engine ought to supply 800 lights. The small number actually in use does not, therefore, develop this problem in any practical way."

"The question of measuring the current," added the Professor, as the reporter turned to leave, "the loss involved from the necessity of running the machinery without a moment's intermission during the entire time that any light is needed—in other words, the absence of any storing capacity for electricity—and various other matters of detail, while less important than the three principal difficulties which I have given you, are, nevertheless, very serious difficulties in the direction of a successful practical application of electricity for general illumination."

BIRDSALL HOLLY.

He Spends a Few Days in Burlington and is Interviewed.

His Opinion of Our Water Works—Edison's Electric Light.

Mr. Birdsall Holly, the inventor of the famous Holly system of water works, arrived in the city from Milwaukee on Saturday, and spent the Sabbath with his nephew, Mr. Ira Holly, the chief engineer and superintendent of the Burlington water works. During his stay in Burlington Mr. Holly was interviewed by THE HAWKEYE, and although he manifested a disposition not to talk when he discovered us making use of a memorandum pencil, we gleaned some points in our conversation that will be as interesting to our readers as they were to us and will be no violation of confidence. Mr. Holly is public property, in one sense, as he has acquired a national reputation as an engineer, mechanic and inventor. He is a prolific inventor, and has had a large number of patents issued to him. He is of tall, robust stature; a man of fine presence, and wears a head upon his shoulders that does not deceive the observer as to the brain power it holds. He is a fine specimen of the American inventor—a fair counterpart, in the world of mechanics, of Edison in the realm of electricity. He is a great admirer of Edison, both personally and as an inventor, and visited him at Menlo Park only two weeks ago. Edison's name started a new theme in the conversation:

Hawkeye—How is Edison's electric light getting along?

Holly—Edison says it is practically complete. There is but little yet to be done before the public exhibition. He asked me to prepare designs for a 250 horse power engine to run his electric generators.

Have you got up some special designs?

Yes; here are drawings of two designs. This is a combined high and low pressure. It is arranged upon a new principle so that the high pressure engine can run at a high rate of speed, and the low pressure or condensing engine at a low speed. Edison thought he would like an engine like the one at Burlington, but probably my new design will be better for his purpose.

How many engines does he intend to use in New York City?

I believe they intend to divide the city up into districts, with four engines of 250 horse power each, or a total of one thousand horse power at each station. There will be a dozen or more stations.

Why couldn't the electric light be introduced into Burlington, if it works well in New York, and use the water works engine for power for the electric generator?

I think that might be done. I believe that is a good idea. The difficulty is that Edison's generator requires a steady power, or, if it varies, it must be in compliance with the necessities of the generator and circuits, or according to the number of lamps in or out of circuit. The water works engine varies in speed, and is governed by the pressure in the mains. But I think a governor could be devised—as, for instance, two cone pulleys—which would regulate the power for the generator to suit its own requirements. It might require delicate mechanism, but I think it could be done. This would get the power almost without expense, as the same engineers, boilers, engine, building, etc., would answer both purposes.

What do you think of the Burlington water works?

I am very much pleased with them. They are run with remarkable economy. I do not think any works in the west can make a better showing. And your works here will do still better when you get more consumers.

You think, then, the true policy for our city is to increase the number of water consumers as rapidly as possible?

Certainly. It is much cheaper in proportion to pump a large amount of water than a small amount. You can double and treble the amount now pumped with no increase in expense for wages, etc., the only added expense being the increased consumption of fuel, and that would be light.

How is your steam heating project getting along?

We are making good progress in the cities where it is now in use, and I think it is destined to come into general use.

Do you think it would pay in Burlington?

I do not know of any place more favorably situated for the system than Burlington. The business portion of your city is concentrated. The principal investment for steam heating is the pipes. It would take but little pipe to reach all the principal business blocks, hotels, and quite a number of factories, printing offices and other places where steam would be wanted for heating, cooking and power purposes. It would not take a great deal of capital to get a company well started here. Two miles of six-inch and four-inch street mains would reach a great many consumers, and make it pay from the start. The mistake made in some cities has been putting in too much pipe to begin with. By laying only enough pipe at first to reach the best patronage but little capital will be required and it will pay.

How many boilers would be needed?

Three or four to start with, and increase as the consumption increases. By putting in furnaces like those at Milwaukee, you can burn soft coal screenings, and run it with very little expense. The Milwaukee furnaces burn the coal without smoke; the smoke is all consumed.

For what purposes could the steam be used?

It would furnish power for engines up to, say, ten horse power; it will cook and bake, and do everything that a stove or range will do; it will heat houses, melt snow in the streets and on the sidewalks, and it is better than water, in many instances, for putting out fires, as you can thrust the nozzle into a room and the steam will penetrate every nook and corner when cold water would only deluge the floor. The day will come when steam will be used the same as water now is for putting out fires, and in cities where steam fire engines are used we will furnish the steam for the engine, thus greatly lessening the weight of the latter by dispensing with the boiler. The light engine, on wheels, will be run to the hydrants and there be supplied with both water and steam. There are a great many other uses to which steam will be put, and it will be supplied to every house the same as water and gas are now supplied.

We learn that quite a number of citizens have the matter under advisement and we have no doubt a company could be organized to put in the steam heating works in Burlington if some one could lead off in the enterprise. It would undoubtedly be another good boom for our manufacturing industries, and we hope the movement will be undertaken.

A NEW STANDARD OF LIGHT.[1]

Nature Dec 18 1879

IN the pamphlet before us we have a proposal for a new form of standard light, and the author has shown some considerable skill in drawing out his method of producing it. We cannot do better than quote his opening paragraph as showing the requisites of a standard that the author deems necessary. He says:—

"No exact measurement of any quantity, even with the most accurate and sensitive test measures available, can reasonably be expected unless the standard by which the unknown quantity is to be gauged is perfectly constant in itself; or if nature does not permit of such a desirable state of things, the causes to which the variation of the standard are due should be known, and in addition also, their quantitative effect on the standard, in order to be able to introduce a correction whenever accuracy of measurement should permit, and circumstances necessitate it."

The want of a standard of light has long been felt in physical researches, and the British Association has acknowledged the impossibility of obtaining scientific measures with the ordinary standards, and has appointed a committee to consider the question of fixing such a standard of white light, that a unit of light may be capable of accurate definition. It must not be forgotten that up to quite recent times the principal necessity for a standard at all has arisen through the introduction of gas into our dwellings and streets, and it has only been necessary to adopt one which should give the comparative illuminating powers of any variable qualities of gas. In fixing such a standard the points to be looked at were (1) that the standard should be capable of easy and exact reproduction; (2) that the colour of the light should be approximately the same; and (3) that in varying states of barometric pressure and temperature, proper corrections in the results of the comparisons should be feasible. It will be seen further on that a fourth desideratum should be introduced for scientific work. Perhaps on no subject has more attention been paid to small details than in the production of a standard candle, and as a result, when burnt under proper conditions, it gives fairly correct values of the illuminating power of gases.

In the record of Mr. Schwendler's experiments with the standard candle as against his new standard of light, we have some startling variations in the light of a standard candle, but we feel sure that, had the proper conditions been observed, there would never have occurred such a tremendous difference as 72 per cent. We are more convinced that ordinary precautions could not have been rigidly observed when we find that some of the comparisons were made after the candle had been freshly lighted. In gas photometry it is well known that the standard candle should burn at least a quarter of an hour before it can be considered to have settled down to a steady light. The standard candle, however, is not a nice unit of light; and two years ago Mr. Vernon Harcourt introduced to the notice of the British Association a gas standard which seems to meet every requirement. By making a mixture in a small gas-holder of one part of the most volatile spirit from American petroleum which distilled at 50° C. with 600 of air, or seven of the vapour with twenty of air, he produced a gas which, whilst almost insoluble in water, was permanent at all ordinary temperatures and pressures, and which was of a known composition and easy of manufacture. A jet of such a gas could be compared with the ordinary coal-gas, and any variations affecting the one would equally affect the other. The colours of the standard and coal-gas lights are also approximately the same. It seems that a standard of such a character meets the requirements for comparing the illuminating value of different coal-gases. Mr. Schwendler proposes to use the light radiated from platinum foil, when raised to incandescence by an electric current, as a new standard, and we agree that a solid instead of a gaseous body as the source of illumination is a step in the right direction. The standards made, however, appear to have been used for determining the illuminating value of the light produced by dynamo-electric machines under varying conditions of speed of armature and resistance in circuit, and it is in reference to this that we will first judge of its probable effectiveness, since for gas measurements the standards already existent suffice. Some dynamo-electric machines are advertised as generating the light of 50,000 candles, and we will suppose for the moment we are comparing such a light with Mr. Schwendler's standard.

Now it may be safely said that a standard candle, farther away than twenty feet from the photometer, would give too small a light to be practically of use as a standard, whilst if approaching the photometer within one foot the magnitude of the illuminating source would seriously affect any accurate results. In the first case the electric light would have to be about 4,500 feet away from the photometer and in the last about 220 feet. For ordinary photometric work even the least of these distances would be objectionable. The platinum standard employed by Mr. Schwendler is only about ·7 of a standard candle, and these distances would have to be increased nearly 20 per cent.

For practical measurements of this description a candle-power of fifty candles is a far preferable value, which it would be difficult to attain by the method proposed. In this case we have the distances reduced, and if the electric lamp is fixed at a distance of 100 feet, we have the movable standard ranging between twenty feet and three to four feet, and the readings become easy and are not subject to be seriously affected by the magnitude of the illuminating source; in fact, the errors of observation then become of larger magnitude than any error arising from this cause. Another point which we have to note is that as far as the colour of the light from the platinum standard is concerned, it possesses very little advantage over the ordinary gas or candle flame, and it would be impossible, or at all events incorrect, to give the illuminating value of a light such as of that produced by the electric arc in terms of the new standard; some recent experiments have demonstrated that the red light emitted by one square mile of the hollow crater in the positive carbon is equal to about the red light radiated by 40,000 standard candles, whilst the mean green light of the former is equal to the mean green light of about 135,000 of the latter, and until such a time as the relative physiological values of green and red light are accurately known it will be impossible to give any true estimate of the illuminating power of the electric light by ordinary photometric comparisons. Both in magnitude and colour, then, the proposed platinum standard of light seems to fail for measuring light produced by high temperatures.

We now turn to the details of the lamp itself. We have, firstly, a U-shaped piece of thin platinum foil cut out about 20 mm. in total length, each limb of the U being about 3 mm. in breadth, the tops of which are clipped in thick metal clips. The usual arrangements are made for passing a current through this foil, the amount being registered by a galvanometer in circuit. A glass shade is also employed for steadying the light, by keeping off convection currents. There seems to be an objection to this form of lamp for accurate scientific work, where it may be necessary to use an *image* of the source of illumination. For instance, in certain spectroscopic comparisons of different lights only a small portion of the image of the incandescent platinum would fall upon the slit. Now the first difficulty that would be met with would be as to the part of the platinum that would emit a standard light. Near the contacts the heat would be conducted away so rapidly that the colour of the light would be of a different tint.

Again, presumably near the middle of the limbs of the U-shaped foil the temperature would be slightly higher than at the outsides; in fact, no two portions of the foil would be exactly at the same temperature.

For work, then, of this class, the standard seems to fail in an important particular.

The writer of this notice made many experiments on this point some years ago, and it was this objection that led him to abandon the idea of a platinum standard light of a form somewhat similar to that of Mr. Schwendler.

For a standard perfectly suited to scientific work, perhaps the following definition will be found tolerably exact:—It should be a body (solid or liquid), some known area of the surface of which can be kept at a high constant temperature. It seems probable that a combination of a body of good with one of a bad conductivity will eventually be found to offer suitable materials for a really trustworthy standard.

It would be unjust to conclude this notice without paying a testimony to the great value of the experiments which have been carried out by Mr. Schwendler in this research. It is quite possible that a modification of his platinum standard may be constructed which will eliminate the defects which are to be found in it. It is certainly a step in advance of the gas or candle standard for everything beyond merely technical work, but it is not of the same accuracy as other scientific units.

W. A.

[1] On a New Standard of Light. By Louis Schwendler. From the *Journal of the Society of Bengal*, vol. xlviii. Part ii. 1879.

Edison's Eureka—The Electric Light at Last.

New York Herald

Herald, Dec. 21 1879

In to-day's HERALD we lay before the public in all its details and completeness what seems to be an absolute solution of one of the most important problems that has fixed the attention of scientific men and inventors in our time—the perfection of the electric light. How shall cities, their streets, public places, churches, theatres and public halls be lighted effectively, agreeably, safely and cheaply? That is an inquiry of dominant importance in municipal administration the world over. And how houses shall be lighted; how the people in their homes shall weather the difficult point of gas, astral oil, gasoline and similar commodities, is one of the grave issues of domestic economy. For a time—for many months together—the people had their hopes exalted on this point, and were led to contemplate the practical application of the electric light to ordinary needs as a boon almost within reach, as a conquest of science not merely possible but so nearly made that it might almost be counted as in the number of the wonderful additions that the progress of discovery has made to the physical comforts of life. And then there was a silence about the wonderful invention, and the chronicle bid fair to end like the history of a shooting star.

Everybody was disappointed. Everybody who watches with interest that material progress in the successful advantages of life upon which depends a great part of what we call civilization, counted the lapse and temporary disappearance of the electric light as an actual loss. It had promised the greatest single advance ever made in the contrivance of artificial methods of illumination, and the failure of the promise left us with a grievous disappointment. In virtue of the glimpses shown in electrical experiments of how near we might be to having in every house these little white stars of the "ethereal essence unoreate," "heaven's first born" of the phenomena of nature, we had come to class all lower artificial lights with the tallow dip and to regard them with the disgust appropriate to unsatisfactory agencies that we had been compelled to cast aside. In fact, all the progress ever made in the improvement of artificial light before the electric light was extremely little, and to merge the yellow and white gaslight with the white and yellow flame of the tallow dip was not an extravagant hyperbole of disappointment. The dip itself was a noble advancement of human invention; but the use of gaslight was taught to man by nature in volcanic countries, where, through crevices in the rocky ribs of the earth, the escaping vapors caught fire. Perhaps there were exceptions to the number of those disappointed by the apparent failure of efforts to utilize electricity in illumination. All persons deeply interested in the welfare of gas companies stood this failure with great fortitude. Panic had seized upon them at the first reports, and the shares of gas companies had shown the common opinion of what were likely to be the financial consequences of success with electricity. But now they were able to contemplate what seemed the futile labors of Edison with self-satisfied complacency. His lamp was even classed already as a "philosophical toy." "Philosophical toy" is the name that has been given in turn to a number of great inventions before the element of cost in them was brought to bear a satisfactory relation to their practical value.

But the story told in our columns to-day will reassure the public whose faith in the "Wizard of Menlo Park" had grown feeble; will revive the general confidence in the future of electricity as the common agent of domestic and public illumination, and may possibly provoke anew the concern of gasmakers. By this story it will be seen that Mr. Edison has finally elaborated a lamp for the use of electricity that is simpler than any lamp in common use in the houses of the people; as simple as the gas burner itself and more manageable; a lamp that cannot leak and fill the house with vile odors or combustible vapors, that cannot explode and that does not need to be filled or trimmed. Once more, therefore, the public may reasonably anticipate a time when they will be free from nearly all the annoyances and grievances of ordinary lighting apparatuses and in the full enjoyment, besides, of a light compared to which every other, save daylight itself, is a mere glimmering and gloaming; compared to which, indeed, even the daylight of about one-third the year is a deteriorated and adulterated article. People generally know the soft glory of the light electricity would make, but they never dreamed of the possibility that it could be applied without an appa-

72

ratus so complicated that it would need a special education to enable them to take care of it.

Perhaps, therefore, this may be regarded as the supreme point of Mr. Edison's achievement in this field—that he has invented a system of such unexpected and remarkable simplicity. His lamp may be screwed on at the end of any ordinary gas burner and the wires from the electric battery may be conveyed to it in the tube that served to convey the gas to the same burner. Whether the wires thus connected come from a battery in another part of the house, or from some larger common reservoir of electricity outside the house, is a point as to which householders will be able to choose for themselves, since both sources are contemplated by the inventor. Mr. Edison, it will be seen in the narrative, has contrived a battery for household use which can be adapted to any different number of lamps and to other uses also—can light the house at night and run the sewing machine or rock the cradle all day. For country houses, or for the houses in the city of people who want to keep themselves out of the clutches of corporations that may succeed the gas companies, that will be the chosen source of electricity. But in every city this subtle fluid will be made on a large scale and served to houses at a fixed price as gas is now served, and of course the street lamps must be served from such great public laboratories.

Edison's discovery of a substance in which electricity could produce the light of incandescence with comparative inexpensiveness and perfect effect is one of those little romances of science with which the pathway to every great invention is strewed. Platinum was a great obstacle for a while in this hunt; and, not altogether satisfactory in operation while of extremely high value, it seemed at the moment as if it might make the search altogether vain. But the happy discovery of the uses of a bit of cotton thread has turned in a moment the whole current of this story into a fortunate channel, and we are rejoiced to congratulate not merely Edison, but the people of all civilized nations, upon Edison's success.

12. From Graham's experiments it may be inferred that, in glowing metals also, there is a greater constant, D, for lighter gases.

PROF. GEIKIE ON THE GEOLOGY OF THE FAR WEST.

AT the opening lecture to his class of Geology, in Edinburgh University, Prof. Geikie gave an account of his recent exploration of the Western territories of North America. He reminded by faults, to what extent they had been twisted, and to what extent ... by atmospheric influences. Getting ... top of these great mountains, he could ... that the strata were almost entirely horiz... for miles, and that the valleys had been trenched ... not of them, not by means of faults at all, but actually by erosion of the surface. He found also that the numerous lakes were true basins of erosion, that they had not been formed by any subterranean movements, but actually gouged out by the ice that once covered those mountains. Striking into one of the valleys, he found beautiful horse-shoe moraines These had gone across the valley and formed a succession of lakes; while the beavers had made a great many more lakes in places not reached by the moraines. In most of these valleys there were hundreds of acres of bog-land, entirely due to the damming of the water by the beavers. The plains in the neighbourhood of the Uintah Mountains were called "Bad Lands," because they were crumbling down under the action of the weather, and nothing would grow upon them. A skeleton, found in a hill of that district, was brought to Professor Marsh, and turned out to be the bones of an extinct and undescribed reptile. From the Uintah Mountains Prof. Geikie found his way north into the Yellowstone country, and examined the fading traces of volcanic action. The volcanoes seemed in that region to have confined themselves very much to the valleys. The heights on either hand consisted of crystalline rocks; the bottom of the valley had been literally deluged with sheets of lava. These were examined with considerable care. In the course of the examination, huge mounds of gravel and stones were met with, which at the first glance were evidently moraines. The first was marked by a huge block of rock, an erratic of coarse granite, different from the rocks round about. Such blocks he found to increase in number as he went up the valley; and on entering the second canyon or gorge, he found the sides exquisitely glaciated. It was clear, therefore, that not only was this second canyon old; it was older than the glacial period. It supplied a channel for the glacier that ground its way out from those mountains. Endeavouring to estimate the minimum thickness of the ice, he traced striæ up to 1,000ft., and they evidently went higher than that. But in going further up the valley, he found that the erratic blocks of granite and gneiss dropped by the glacier as it melted went far above the 1,000ft. limit; he got them on the shoulder of one of the great hills overlooking the valley 1,600 or 1,700 feet above the bottom of the valley; the ice, therefore, must have been 1,600ft. or 1,700ft. thick. It thus appeared that not only did those mountains possess glaciers, but some of these were of such thickness as to deserve the name of ice-sheets, covering the whole surrounding region. As to the volcanic phenomena of the district, he saw evidence of a long series of eruptions, one after another, separated by prolonged intervals, during which the river went at work cutting out the older lavas, the newer lavas filling up the hollows eroded by the river. In the grand canyon of the Yellowstone, he saw the most marvellous piece of mineral colour anywhere to be seen in the world. It was cut out of tuffs and lavas, showing sulphur yellow, green, vermilion, crimson, and orange tints, so marvellous that it was impossible to transfer them to paper. Leaving the Yellowstone Valley, he struck south-westward into the famous geyser regions, where a number of geysers had been made known of late years more wonderful than those of Iceland. He tried hard here to get a pool to wash in, but could find nothing below 212°, and the only chance of getting a bath was to get into some hole where the water had had time to cool after flowing out of the hot crater. The whole ground was honeycombed with holes, every one of which was filled with gurgling, boiling water. Some went off with wonderful regularity, others were more capricious; and the chief geyser, which threw up an enormous body of water and steam, was very uncertain in its movements. In one part of the district he came upon a marvellous mud spring, the centre of it boiling like a great porridge pot full of white and very pasty porridge. Steam rose through this, and, after forming great bubbles, burst, the mud thrown out forming a sort of rim round the crater. After describing a meeting with Indians on their way to a great council, the Professor said his road after that lay across what he supposed was one of the most wonderful lava fields in the world—hundreds and thousands of square miles of country—a sort of rough plain—having been absolutely deluged with lava. How this lava was poured out he at present could hardly tell; it seemed to have risen through long fissures, and spread out so as to fill a vast area. Here and there along the margin of it were distinct volcanic mounds, apparently formed during later stages of its ... Coming at length to the Salt Lake territory, one of the ... the former vast ... that struck him was the evidence ... expansion of the Salt Lake ... [illegible] tains, about 1,000ft. above the present level, and he succeeded in discovering what was the relation between the extended lake, which must have been a great many times larger than the present one, and 1,000ft. deeper, and the glaciers which at one time covered the Wahsatch and the Yellowstone Mountains. Striking into some of the canyons descending from the Wahsatch into the Salt Lake basin, he found evidence of wonderful glaciation. The rocks were smoothed and polished and striated by the glaciers that had come down from the heights, and these glaciers had carried with them great quantities of moraine matter. Huge mounds of rubbish blocked up the valleys here and there, and these mounds came down to the level of the highest terrace. That was to say, that, when the Salt Lake extended far beyond its present area, and was over 1,000ft. deeper than now, the glaciers from the Wahsatch Mountains came down to its edge and shed their bergs over its waters. On his return journey the Professor resumed the examination of the prairies. Coming out of the Colorado Mountains, he noted, in connection with the gravel formerly observed, great quantities of a peculiar grey clay. This clay was inter-stratified with the gravel, and here and there contained a small lacustrine, or terrestrial shell. It was, therefore, a fresh-water deposit, a deposit swept by the waters coming down from the mountains over the prairie; and marked an interval in the period during which the gravel and sand were being thrown down. He traced the gravel mounds over an extensive tract, and he found the gravel had been deposited irregularly, just as would have been the case from the action of water escaping from the melting ends of the ice. A great current would traverse the plain in one direction; then the ice mass would send water in another, so that the whole prairie must have been flooded with water derived from the melting ends of the vast sheets of ice. It was those excessive floods that brought down the gravel and sand; and during that time there were intervals when nothing but the finest mud was coming down, just as was seen in the valleys of the Rhine and Danube.

EDISON'S RESONANT TUNING FORK.

THE following description of a resonant tuning-fork is given by Mr. T. A. Edison:—For the purpose of rendering audible the sounds produced by tuning-forks they are generally mounted upon resonant boxes containing a column of air, whose vibrating period is the same as that of the fork. I have devised a modification,

in which the box is dispensed with, the resonant chamber being formed by the prongs themselves. To make the fork, a thick bell-metal tube has one end closed, a slit is sawed through the centre of the tube nearly to the closed end. This divides the tube and gives two vibratory prongs. To bring the prongs in unison with the column of air between them the tube is put in a lathe and turned thinner until unison is attained, whereupon the sound is powerfully reinforced.

SOME RECENT ADVANCES IN TELEGRAPHY.—IV.*

NOW, as to that which supports the wire. Wires are suspended along the line from pole to pole at distances of about 80 yards; and at every point where the wire rests against the pole (the pole itself being a conductor), if it were not protected in some way, the electricity passing through the wire would fly to the earth and disappear. I told you that on the first line the insulator that was used was a goose-quill. This was speedily replaced by an ordinary earthenware ring; and from that day to this changes have been going on—from rings to cups of all kinds and forms, made of either earthenware, glass, white porcelain, black ebonite, or any other material that the genius of the inventor or manufacturer could bring forward. In this field we have been taught what to use solely by experience. From 1840 to the present day, everybody who has had anything to do with telegraphy has been devising some dodge by which the power of our insulators can be improved; and the concentration of experience of telegraph engineers all over the world has been to show that

WERDERMANN'S ELECTRO-MAGNETIC ENGINE.

Telegraphic Jne 1.5.79

ALTHOUGH many attempts have been, and are being, made to obtain motive power by means of electricity, but very little success can be said to have been attained. As an economical source of power, electricity cannot by any means be said to have established itself, and there does not yet seem any prospect of its doing so. It is not necessary here to enter into any details concerning the relative costs of motive power, produced by combustion of coal in a steam engine, or of metals and acids in a battery. The extreme unfavourableness of the comparison, as regards the latter, is too well known to need repetition. It is quite possible that considerable use may be made of waste chemical products for producing electricity to obtain motive power, but such cases must be comparatively few, and but very lightly touch upon the general question.

There is, however, a question in which electricity will assuredly play, ere long, a very prominent part, and that is in the "conveyance of motive power to a distance." Should this problem be satisfactorily solved, the enormous sources of power produced by the operations of nature, in the ebb and flow of the tide for instance, which are useless to a great extent, because these operations take effect at places far removed from localities where the power is most required, would be laid under tribute.

The problem has, to a very great extent, been solved by the very great success which has been attained in the means for producing dynamic electricity in the machines of Siemens, Gramme, &c. Given the motive power, we have here the machines necessary and able to convert it into dynamic electricity; the conveyance of the latter to a distance is only a question of stout insulated metallic wires or rods, and it possesses no points of great difficulty. There only remains then the machine to reconvert the electric stream into motive power, and the question is in a very fair way to be solved.

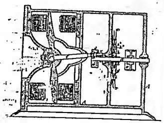
Among the many attempts that have been made in this direction, may be noticed the machine of Mr. Werdermann which possesses several points of novelty worth being pointed out.

In this machine three or more electro-magnets are arranged in a circle with their axes parallel to a main shaft which traverses the centre of an iron plate or disc, on which are fixed the electro-magnets.

In front of the poles of these electro-magnets an oscillating armature, preferably in the form of an obtuse cone, is arranged, provided at the apex with a short shaft and in the centre of its basis with a spherical bearing or universal joint. The shaft fits in a bush of copper or brass, or any other suitable non-magnetic material, fitted to the crank arm which is keyed on the main shaft, while the spherical bearing, made of non-magnetic material, enters a hole cut out at the apex of another disc which is connected with the frame of the apparatus.

On the main shaft is fixed a driving pulley. The shaft also carries a current breaker, which consists of two discs of ebonite or lignum vitæ, or other suitable non-conducting material, a segment of each being replaced by copper or brass, or other suitable conducting material, and connected with a ring of copper. The two discs are insulated from each other and are in contact at the periphery, each with as many springs, rollers, or rubbers as there are electro-magnets. The periphery of each ring is in contact with another spring, roller, or rubber, one of which is connected with the positive and the other with the negative pole of a galvanic battery or other generator of electricity.

The electric current flows through the rings,



segments, rollers, and the coils of the electro-magnets, which in succession, singly, or in series, attract the conical armature, thus forcing the crank pin to move in a circle, or, rather, to develope a cone, through the axis of which passes the main shaft, imparting to it a rotary motion.

The current or contact breaker is adjusted in such a manner that at the moment when one of the electro-magnets is in contact with the cone, the circuit is broken, the contact rollers passing from the copper segment to the insulating surface of the ebonite discs.

In order to obtain the largest possible surface, the polar extensions may be cut obliquely, so that their surface may have the form of an ellipse, or the cone may be provided with as many hemispherical or other projections as there are electro-magnets, the polar extensions of which must be concave or otherwise suitably formed to receive the said projections.

By preference, electro-magnets of a novel construction are employed in the machine; they are composed of an iron cylinder or tube fixed on a bottom plate, coiled with copper wire, or ribbons, or sheets of copper, and placed inside another iron tube, which is also coiled with copper wire, but in an opposite direction, so that the outer tube assumes opposite polarity to that of the inner tube; or, between two concentric tubes of suitable diameter, coiled with copper wire in such a manner that they have both the same polarity, may be inserted a series of cylinders or smaller tubes, coiled with copper wire in such a manner that the cylinders or tubes have all the same polarity, but an opposite polarity to that of the two large tubes, between the peripheries of which they are placed. The two concentric tubes are always magnetised, in fact, they may be permanent magnets, while the smaller magnets are magnetised or demagnetised in succession.

The figure shews a longitudinal section of the engine.

A is a frame of cast iron or other suitable material; a, a^1, are discs or plates forming part of or secured to the frame. The disc a carries one series of electro-magnets b, and the other disc a^1 carries another series of electro-magnets b^1; c is the armature; d is the main shaft of the engines; e is a driving pulley on the shaft.

Two series of three or more electro-magnets b, b^1 are employed, arranged in a circle, with their axes parallel to the main shaft d. Between the poles of these two series of electro-magnets, the oscillating armature c is arranged, which is preferably of the form shewn, and is provided with a central shaft f; one end f^1 of this shaft projects from the centre of the base of the armature c, and is fitted into a bearing g in such a manner as to form therewith a universal joint. This bearing g is formed of non-magnetic material, and is secured in a part of the frame as shewn. The other end f^2 of the shaft f fits in a bush i of copper or brass or other suitable non-magnetic material connected with a crank arm or disc j, which is keyed on the said main shaft d.

The main shaft, besides carrying the driving pulley e, also carries a current breaker k, which consists of a disc k^1 of ebonite or lignum vitæ or other suitable non-conducting material; a segment of this disc is removed, and replaced by copper or brass or other suitable conducting material as shewn at k^2, and connected with a ring k^3 of copper. The communicator k at its periphery is in contact with as many springs, rollers, or rubbers l, as there are electro-magnets in each series. The periphery of each ring k^3 is in contact with another spring, roller, or rubber, one of which is connected with the positive and the other with the negative pole of a galvanic battery or other generator of electricity.

The electric current flows through the said rings, segments, and rollers, and the coils of the electro-magnets, b, b^1, which in succession, singly or in series, attract the conical armature c, thus forcing the end f^2 of the shaft f to move in a circle, or rather to develope a cone, through the axis of which passes the main shaft d, and thereby impart a rotary motion to the said shaft.

The current or contact breaker k is adjusted in such a manner, that at the moment when one of the electro-magnets is in contact with the oscillating armature the circuit is broken, the contact roller passing from the copper segment to the insulating surface of the ebonite disc.

Sci Amer Dec 6 1879

EDISON'S ELECTRICAL GENERATOR.

To the Editor of the Scientific American:

The letter of Mr. Upton, on page 337, is far from being satisfactory, at least to myself, for it tends to frustrate the realization of the plans I had suggested of relieving Mr. Edison from the appearance of having put forth a preposterous claim for his electric generator. It has almost brought me into the thick of a controversy; I barely escape and reserve my valor for another day. I protest that up to this time I do not know that there is any disagreement between Mr. Edison and myself. Mr. Upton is indeed Mr. Edison's assistant, and his letter purports to be authorized, and yet I cannot find anywhere irrefragable proof that Mr. Edison is the author of the preposterous claim, or that he ever indorsed it. I believe it is best, indeed, as I did in my article on page 305, to assume, until its falsity is proved, that Mr. Edison in the matter of that preposterous claim, or anything else, has not treated with indignity the revered memories of Ohm, Faraday, and the other fathers of electricity. Mr. Edison, like myself, appears to love peace and quietness, and perhaps the guilty author of that preposterous claim will never be discovered and punished. The disagreement which so far is developed is between Mr. Upton and myself only, and it will not long continue if he will take my advice.

The matter in Mr. Upton's letter which is offered as especially pertinent to the preposterous claim is comprised in the two following sentences:

1. "The writer of the article (on page 242) simply stated that the machine was so constructed that when used at its normal capacity the exterior resistance shall be nine times as great as the internal, so that ninety per cent of the power of the current would be used outside."

2. "Yet all that was claimed in the article (page 242) was perfectly true, and has been carefully verified."

I have not been able to satisfy myself as to what are the intent and meaning of sentence 1. I cannot find out what "normal capacity" is. I cannot find out what the thing is which was simply stated; why did not Mr. Upton state it simply? Among various theories of the intent of sentence 1 which I have worked out, the most plausible is, that the sentence is a device like those terrible engines which Knickerbocker, in his history of New York, relates were employed by the ponderous Dutch warriors. This theory derives confirmation from the fact, which appears on page 308, that Mr. Upton found it a fair thing to fire, without warning, at short range, and point blank, but shot of Calculus (!) right into a gentleman by the name of Weston.

But sentence 2 is direct, explicit, and emphatic. It is so admirable in its way that I quote it again: "Yet *all* that was *claimed* in the article was *perfectly* true, and was *carefully* verified." Now, as nothing was claimed (on 242) but what is covered by the preposterous claim, this latter is signed, sealed, and indorsed; it is represented as having been verified; it is reasserted strenuously. Did Mr. Upton pen that sentence, with the demonstration on page 305 before his eyes?

I reproduce, from page 242, the preposterous claim: "Mr. Edison claims that he realizes ninety per cent of the power applied to this machine in effective external current," and thereupon soon follows the explanation that the great economy is due to the employing of a resistance ratio of 1 : 9. For the demonstration of the fallacy of this I refer to page 305.

I might stop here, for I have said all that is required concerning the matter of the preposterous claim. Mr. Upton introduces several other and extraneous things which are calculated, like that sentence 1, to befog and lead astray the hasty reader, and I shall therefore briefly notice them. The larger part of the letter is devoted to remarks which are aimed more or less directly at myself personally. The general effect of these is substantially that of the trite retort, you're another; but I meet them in detail by pointing out that a part are intended to show that I had overlooked something important, and the rest that I use technical terms ignorantly and recklessly.

1. After a very ingenious prelude, in which I am made to take a rather funny part, the following climax is reached: "It seems never to have occurred to the doctor that it is in the power of the maker of the machine to exert this 'moral suasion' on the wire covering the armature, so that it shall be more effective and redouble its exertion when greater resistance is offered for it to overcome." Mr. Upton is correct; it really never did occur to me. But feeling that such a confession, on account of its brevity, is rather weak, I append the remarks of one whose opinions are worth their weight in diamonds, and are the delight of the world: "If so be ye overhaul yer masheen, tack on yer [illegible] wire, and make them irons, which ye call magnets, a leetle hoftier, why then yer masheen will be bigger; and howbeit ye do these things, why ye'll have a bigger masheen. Bigger, did I say? No! Why? For the bearings of the observation is in the application on it." This is perhaps one of Bunsby's greatest efforts.

2. Mr. Upton neatly gets round to the remark that I deliberately state that current and foot pounds are the same, that energy is directly proportional to the current, etc., and he corrects and instructs me by remarking that "foot pounds are always meas[ur]ed by the square of the current," etc. Moreover, he says: "Dr. Seeley's distinction of outside from inside current seems to me ridiculous." Mr. Upton, no doubt, made himself quite merry at the discovery of all the blunders of mine. Now I reply: Mr. Upton would not have discovered those blunders unless he had been looking for them; the wish is father to the thought. I do not think anybody else h[as f]ound them, or is likely to find them. When we are obli[ged] to write in the telegraphic style, as we are when limited as to time and space, we spontaneously take up abbreviated expressions which hypercritics might object to. Thus we may use the letter C for current or strength of current or energy of current, and no one but the hypercritics will misunderstand or complain unless some positive ambiguity results. Life is too short to write with a view of satisfying the hypercritics. I might quote many precedents for the expressions I used, but I content myself with a single one, for the reason that it is from an authority which, I am sure, Mr. Upton greatly respects; the authority, please understand, is not Mr. Edison: possibly it is Mr. Upton himself. If Mr. Upton will turn to page 242 he will find there the preposterous claim as originally propo[unded, an]d he will observe that the last two words are "[illegible]." How is it now? Will Mr. Upton ever again say, "[Dr. Seeley's distinction] of outside from inside current se[ems] to me rid[iculous]"?

After finishing my case, Mr. [Upton says]: "In conclusion, I may state that the method[s] [illegible] employed for testing Mr. Edison's machines w[ere] fully described in a paper read by me (in August) at the Saratoga meeting of the American Association. At that time (in August), as now, full results were withheld until Mr. Edison was fully satisfied with the performance of the machine." I find [in] this pretty plain evidence that Mr. Edison did not—and this I have contended for from the first—put forth the preposterous claim. He had full tests in August as well as on October 11th, and of course he knew that he did not realize that 90 per cent; if he had realized it, he would have been fully satisfied with the performance of his machine, for his machine would be the greatest invention of all time.

Mr. Upton concludes by mentioning that Mr. Edison hopes soon to have a machine with a resistance ratio of 1 : 20. I trust this is not quite true. It would be almost a public calamity if Mr. Edison should employ his great talent on such a puerility. I quote again: "His machine is so made that it would be impossible to use it with the same resistance outside as inside, as it would heat the wire on the armature so as almost to burn it, by carrying a current so much in excess of that for which it was intended." The truth of this must be evident to any one who is a tolerable expert on machines; but I quote it as further evidence that Mr. Edison is not the author of the preposterous claim, and to raise the [question] whether we cannot relieve Mr. Upton also from authorship.

A few weeks since (suppose) the startling announcement was made in the papers that X, a dear and distinguished friend of mine, had lifted himself over a tall fence by pulling on his boot straps. Many respectable people, influenced mainly by their exalted and often proved faith in the ability of X, accepted the announcement as true; for my friend was an eminent authority and exceedingly expert in the matters relating to the alleged achievement. The hopeful people at once began speculations on the applications of X's discovery to rapid transit and other great projects. The larger part of the community, however, remembering something of the little lessons in natural philosophy of their school days, denied the claims set up for X, and they scoffed at him. At this juncture it seemed to me a proper thing and a duty towards a friend and to the public to make an explanation. I said that the feat proclaimed was really an impossibility, that it was a contradiction of the law of action and reaction; that the pulling up on the boot strap would be precisely balanced by the pressing down of the feet in the boots, etc.; that my friend was of too good sense to claim impossible performances; that the announcement was an exaggeration, or came from a wicked partner, etc. My explanation was calculated to pacify the scoffers and to make all lovely again. My friend had no call to say anything, unless to [pra]ise my explanation or to turn the whole affair into mild but pleasing entertainment by relating how the announcement originated in a little badinage of his, in which he proposed to lift himself over the fence, by pulling o[n his] boot straps [illegible] his carriage after slinging them over a [illegible], etc. But the affair is going to terminate differently [and] sadly. For a gentleman by the name of Z, who is an assistant (some say a partner) of X, has written a letter to the public w[hich] purports to be authorized by X, in which the original claim is reasserted and enlarged. Mr. Z says: "Spring, at its normal capacity, is the pleasantest season of the year. X never denied Newton's laws. Yet all that was claimed in the papers was perfectly true, and has been carefully verified. X has positively lifted himself over a fence ten feet high, and it may be mentioned that he hopes to lift himself over a fence 20 feet high. There are doors in the fence, but there [are] patent locks on them. (What does this mean?) This [illegible] doctor, and I wouldn't trust him with a [illegible] [illegible] problem with a G, and this name is mentioned [in conn]ection with a neighbor's hen roost." This letter [illegible] great [illegible] to us, but I protest and persist that [illegible] innocent [illegible] can foretell what is to come out of this [illegible].

But all this is supposition. [illegible] n't apropos of anything. "The bearings of an observation is in the application on it."

CHARLES A. SEELEY.

A Note from Mr. Edison.—The Hughes Microphone and the Blake Transmitter.

To the Editor of the Scientific American:

In reference to the communication from T. D. Lockwood, which appeared in the SCIENTIFIC AMERICAN (No. 21), November 22, 1879, regarding the carbon telephone, I wish to say that his statement that the scientific men of Europe have supported the claim of Hughes that the microphonic action is different from the carbon telephone, is absolutely false, and as a fact just the contrary is the case. Also that the Patent Office has declared that the Blake transmitter filed in the Patent Office in 1879 infringes several of my patents filed in 1877. In fact there is not the slightest difference between the carbon transmitter and the so-called Blake transmitter, except in size of parts and delicacy of adjustment.

HEINRICHS' ELECTRIC LAMP.

Telegraphic Journal Oct 15 1879

By C. F. HEINRICHS.

THERE have been lately many systems of electric lighting shown to the public, in which the production of small lights for the purpose of superseding gas has been quite successfully effected; but, from a financial point, they have not been quite satisfactory, as the unpracticability of the subdivision of the electric current for lighting purposes without loss has been often proved.

The only field in which electric lighting has already superseded gas, both as regards its being superior in illuminating power, and also its being actually cheaper than gas, has been where large lights (1,000 to 6,000 candle power) have been employed, and in which the consumption of the carbon pencils has been regulated by clockwork.

The only drawback in this line has been the inefficiency of the regulating mechanism; thus the light becomes extinguished frequently, and in some lamps it takes from 4 to 10 seconds before they are relit, and a disagreeable flicker is the result.

In almost all regulators, where the consumption of the carbon is regulated by clockwork, in conjunction with an electro-magnet, the current which produces the light has to pass through this magnet, and the increase or decrease of the current increases or decreases the attracting power on the armature of the same, which stops or releases the clockwork. I have found always that when the armature releases the clockwork and the carbon feed, the increase of the current does not take effect at once, not in proportion to the feed, and not until the arc covers again sufficiently and equally the new advanced mass of the positive carbon, and this sometimes takes from 2 to 10 seconds of time. Now in this time the clockwork is free, and the carbons keep feeding, and, therefore, are liable to come too close together, which produces the disagreeable hissing noise so often observed; or else, by the carbons coming quite together, the great increase in the current flowing in the circuit causes the generator to become heated, and its insulation thereby to be impaired.

That the increase of the current does not take effect at once when the carbons feed, will be explained by the fact that the heated carbon is a better conductor than the cold, therefore the current cannot rise to its maximum power until the new advanced mass of carbon is equally heated, and not until then does the arc equally cover the positive carbon; when again the arc becomes most conductive, and the current most powerful, then by its acting upon the armature of the magnet, it prevents the carbon from further feeding.

It will, therefore, be evident that regulators should be so constructed that when they are extinguished by accident they shall re-light instantaneously; and, secondly, that the carbon points shall never come actually in contact while burning.

The last point has been already effected by the candles of Jablochkoff, Wilde, &c., in which the arc is kept always of the same length. But these candles burn only with alternate currents, and the continuous currents have always proved their superiority in light power against alternate currents; also as

are used, all four points will become nearly pointed. Fig. 5 shows the candle arranged on a lamp post, the carbon points, in this case, being set upwards. These candles may be constructed for any size of light, and will burn from 10 to 24 hours without change of carbon; in fact, an advantage is gained by their being made in that shape. It is very difficult to make long carbons accurately straight, and unless they are so the points will not preserve their proper position relative to one another when set in the lamp. The circular carbons being made in the form of a ring, and then cut into two parts, accurately keep their annular form, and always, therefore, will burn with their points in the same relative position.

An important point attained by the use of the circular carbons is economy of space and portability; when straight carbons are used, it is evident that the length of the space occupied by the lamp cannot be less than that of the two carbons, whereas with the circular carbons the length occupied is reduced to less than one-third, thus rendering the lamp very compact. Practically, also, it must be evident that long carbons could be used without inconvenience, and thus the lamp could be kept burning for a very long time without renewals. The manufacture of the circular carbons presents no difficulty whatever.

The whole system is most economical for lighting public halls and large open places, as the lamps can be fixed at an unusual height, with a reflector and glass globe, so that rain, wind and dust would have no effect, whilst they will cast their light to a long distance.

PRODUCTS OF THE VOLTAIC ARC.

Shortly before his death, the late Professor T. Wills, of Greenwich Naval College, made the important discovery that nitric oxide is formed in the voltaic arc. More recently Professor James Dewar, of the Royal Institution, has determined the curious fact that hydrocyanic, or prussic acid, that deadly poison, usually distilled from laurel leaves or bitter almonds, is formed in small quantities in the voltaic arc.

A series of experiments favouring the conclusion that the so-called carbon lines are invariably associated with the formation of acetylene (as suggested by Plucker, Angstrom, and Thalén) induced Professor Dewar to make some experiments to ascertain whether this substance can be extracted from the electric arc, which invariably shows this peculiar spectrum at the positive pole, when it is powerful, and occasionally intermittent. For this purpose the carbons were used in the form of tubes, so that a current of air could be drawn by means of an aspirator through either pole, and the products thus extracted from the arc, collected in water, alkalies, and other absorbents. Gases may be led through one of the poles, and suction induced through the other, in order to examine their effect on the arc. The experiments were made by means of the Siemens' and De Méritens' magneto machines. Hydrogen led in by the positive pole, and the gases extracted, gave the well-known acetylene compound with ammoniacal sub-chloride of copper; while, at the same time, a wash-bottle containing water gave distinct evidences of the presence of hydrocyanic acid. Air drawn through the negative carbon gave considerable quantities of hydrocyanic acid, which was greatly increased by extracting the gases through the positive carbon. Carbons purified in chlorine and hydrogen gave with De Méritens' nothing; with Siemens', and a draught of air through the negative pole, a small quantity of hydrocyanic acid, but a larger yield when positive was used. The gases extracted after the absorption of the hydrocyanic acid contained acetylene. If the carbons are not purified, sulphuretted hydrogen is always found along with other gases. The inference to be drawn from these experiments is that the high temperature of the positive pole is required to produce the reaction, which is in all probability the result of acetylene reacting with free nitrogen, as when induction sparks are passed through the mixed gases, viz.: $C_2H_2 + N_2 = 2HCN$, and that the hydrogen is obtained from the decomposition of aqueous vapour and the combined hydrogen in the carbons. It is possible traces of alkaline salts in the carbon poles may favour the formation of hydrocyanic acid, but, as all attempts to purify the poles so as to stop the reaction failed, I am inclined to believe it is a direct synthesis. The acetylene reaction is one of the many remarkable syntheses discovered by Professor Berthelot, of Paris. The presence of sulphuretted hydrogen is doubtless due to the reduction of the sulphates, invariably present in the ash of the carbon. A more complete examination of the various reactions to be brought about by means of the Siemens' arc, and with poles of varied composition, and in presence of different gases, will be communicated to the society in a subsequent paper.

The hard diamond-like deposit of carbon, which after a short time is found to obscure the interior of the globe of an incandescent carbon electric lamp, like the Sawyer-Mann, has also been made the subject of analysis by Mr. B. S. Proctor. The lamp examined was made by Mr. J. W. Sivan, and exhibited to the Newcastle Chemical Society in December last year. It consisted of a glass flask, which after being filled with nitrogen was exhausted by a Sprengel, and an incandescent pencil of carbon. It was, therefore, supposed to contain nothing which could carry carbon from the glowing pencil to the cooler surface of the glass around it. Platinum contacts were employed to connect the current with the carbon.

Under the microscope the smoky deposit on the glass showed numerous bright globules, no doubt of platinum, and more minute particles of dark matter, nebulous, under a $\frac{1}{4}$-inch objective. On exposing the glass to an oxidising heat, the deposit partially disappeared, still leaving the glass partially darkened however.

The platinum supports was coated with dark sublimate. The deposit on the glass was not entirely dissolved by *aqua-regia*, and analysis showed that the soot contained platinum, carbon, and iron. The platinum globules might result from the disruptive discharge which took place at the moment the lamp failed

CHRONIQUE DE LA LUMIÈRE ÉLECTRIQUE

La Correspondance Scientifique 2 déc

Des expériences comparatives vont avoir lieu cette semaine, croyons-nous, à l'Opéra et dans une des salles de la gare Saint-Lazare, d'une part, entre la bougie Jablochkoff et la lampe Werderman, et, d'autre part, entre cette même bougie — qui est devenue aujourd'hui un véritable point de comparaison — et les lampes Lontin et Seimens.

Ces expériences, dont il est facile de prévoir le résultat, permettront de fixer le public sur la valeur des systèmes employés.

Nous disons à dessein le *public*, car, depuis longtemps, les électriciens ont une opinion faite sur ces lampes à mécanisme compliqué et à fonctionnement irrégulier que l'on nous a présentées ces temps derniers, avec une exagération intolérable de réclames.

A ce propos, nous ne pouvons nous empêcher de regretter la façon dont M. Siemens ou plutôt son représentant a cru devoir, au palais de l'Industrie, attirer l'attention publique. Le bout de l'oreille passait de telle sorte qu'il était impossible de s'y tromper : on voulait prouver que la lampe Seimens pouvait et devait avantageusement remplacer la bougie Jablochkoff.

Ainsi que nous le disions haut, c'était la bougie Jablochkoff que l'on désignait comme mesure de comparaison, en montrant au public quelques luminaires d'une lumière pâle et vacillante.

***

Le monde savant est assez étonné de voir décerner un diplôme d'honneur à la compagnie Lontin, alors surtout que le jury de la classe de l'électricité était généralement composé d'hommes compétents, très au courant des choses relatives à la lumière électrique. Nous croyons être bien renseignés en disant que le jury n'est pour rien dans la haute distinction accordée à M. Lontin et que celui-ci aurait tort de se prévaloir outre mesure de ce diplôme d'honneur. Il nous paraît inutile, quant à présent, d'insister sur ce sujet; nous y reviendrons s'il le faut, et nous y reviendrons avec d'autant plus de connaissance de cause, que M. Ch. Varey, notre rédacteur en chef, faisait partie de ce jury.

***

Cela dit, nous ajouterons que toutes les expériences que l'on pourra faire ne nous déplaisent en aucune façon, elles sont même utiles dans certains cas, ne serait-ce que pour provoquer le silence de certains inventeurs turbulents ou de sociétés financières auxquelles les succès des autres portait envie.

En attendant que nous puissions consacrer une étude sérieuse aux expériences qui vont se produire dans d'excellentes conditions aussi bien au point de vue pratique qu'au point de vue économique, nous sommes heureux d'annoncer à nos lecteurs que la bougie Jablochkoff fait à Londres des progrès considérables. Elle vient d'entrer, et d'entrer par la grande porte, dans l'éclairage privé. Ce n'est plus seulement la voie publique qui est éclairée à Londres par cette splendide lumière, mais de nombreux établissements particuliers. Et remarquez que le succès n'est venu qu'après la réussite des expériences entreprises sur les quais de la Tamise. Les Anglais ne s'enthousiasment pas facilement — et ils ont raison. Lorsqu'ils adoptent une invention, c'est que la démonstration de la valeur est positivement sérieusement faite. En lisant cette semaine, dans les journaux scientifiques anglais, la marche progressive de l'emploi de la bougie Jablochkoff, je me suis rappelé les lignes écrites par M. le comte du Moncel dans son livre si intéressant, l'*Eclairage électrique*, lignes qu'il nous paraît opportun de rappeler, en ces temps de singulières revendications :

« C'est grâce à elles et à la puissante Compagnie qui s'est organisée pour exploiter cette invention — écrivait l'éminent électricien, en parlant de la bougie Jablochkoff — qu'on a pu entreprendre ces belles expériences et ces éclairages splendides de l'avenue de l'Opéra, de l'Arc-de-Triomphe de l'Etoile, de la Chambre des députés, des magasins du Louvre, du théâtre du Châtelet, etc., etc., qui ont émerveillé tous les étrangers qui sont venus à Paris lors de l'Exposition de 1878, et ont démontré que l'éclairage électrique n'était pas une chimère comme avaient voulu le prétendre les intéressés des compagnies du gaz. Enfin ce sont elles qui ont provoqué cet engouement général de tous les pays pour l'éclairage électrique, qui amènera fatalement d'ici à peu de temps la substitution au moins partielle de l'éclairage électrique à l'éclairage au gaz. »

A. de Rupembert.

EXPOSITION DES SCIENCES

APPLIQUÉES A L'INDUSTRIE

La Science pour tous 29 1879

Exposition Lontin.

La production du fluide électrique à bas prix n'est pas le seul problème que doive poursuivre l'ingénieur électricien, il faut en outre qu'il songe à utiliser ce fluide de la manière la plus avantageuse et la plus complète.

La transformation du fluide en lumière a lieu soit par la combustion de baguettes de charbon, sous l'influence des courants électriques, soit par l'incandescence du platine porté au blanc éblouissant, suite de son échauffement sous l'action de ces mêmes courants.

Fig. 158. — Régulateur automatique pour lampe à incandescence de fil de platine.

Dans le premier cas, les appareils employés sont basés sur le même principe que les autres lampes électriques déjà décrites de Jablochkoff, Werdermann, Reynier, etc. Ils consistent en baguettes de charbon poussées automatiquement l'une contre l'autre, entre les extrémités desquelles jaillit l'étincelle lumineuse. En réunissant, comme le montre la figure 160, quatre systèmes de baguettes de charbon rayonnant vers un centre unique, sans se toucher, on obtient ce que M. Lontin appelle un soleil électrique. Quatre courants sont envoyés dans ces quatre charbons, de manière à donner naissance à quatre étincelles ou plutôt à quatre arcs voltaïques qui se confondent pour former un seul point lumineux d'une intensité prodigieuse.

Un phénomène curieux se produit si l'on vient à écarter les charbons les uns des autres : des flammes jaillissent, non pas avec amoindrissement de lumière, comme cela se

…présente dans les cas ordinaires, mais avec accroissement notable. Ces flammes peuvent atteindre quinze centimètres de longueur, et affectent la forme fourchue. On ignore, paraît-il, la vraie cause de ce phénomène, qui est le contraire de ce que l'on connaît de l'arc voltaïque lumineux, quand il se présente dans les autres lampes électriques.

On peut également, avons-nous dit, produire la lumière électrique en élevant la température du platine jusqu'au blanc éblouissant. Dans ce cas, le fil dont on doit élever la température n'est pas rectiligne, mais il est contourné en spirale, les deux extrémités de cette spirale sont fixées dans les trous de deux bornes de cuivre où les serrent fortement des vis à tête aplatie.

Ce mode d'utilisation de la lumière électrique est moins favorable et plus coûteux que la combustion des charbons, mais il présente des avantages dans certaines circonstances.

Mais quand on fait passer un courant électrique sur un fil fin de platine, la température de ce fil peut s'élever à un point tel que le métal peut se rompre, brûler ou se volatiliser. C'est là le plus grand obstacle à l'utilisation de l'incandescence du métal comme foyer lumineux. Le physicien Edison, aujourd'hui illustre, a essayé de corriger cet inconvénient, mais il n'a pu y réussir. On comprend en effet que si, pour une cause ou pour une autre, la quantité de fluide ou sa tension augmente, la chaleur du platine s'élèvera à un point exagéré, et un accident pourra se produire. M. Lontin a obvié à cet inconvénient au moyen d'un régulateur à jeu automatique de type spécial (fig. 158).

Cet appareil est disposé de telle sorte, que si l'intensité du courant s'accroît outre mesure, le jeu d'un électro-aimant attire un petit bouton de fer, qui ouvre au courant une voie de dégagement et interrompt son passage dans le fil de platine.

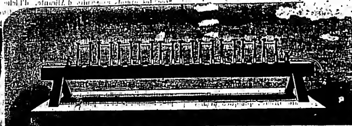

Fig. 159. — Rampe de dix lampes à spirales incandescentes.

Ce fil se refroidit, le régulateur cesse alors d'interrompre le passage du fluide, la spirale redevient lumineuse et éclairante. La même manœuvre se reproduit toutes les fois que l'électro-aimant est influencé par le courant, ce qui a lieu lorsque la force de ce courant atteint un certain degré, le degré nécessaire pour mettre … ou l'électro-aimant du régulateur.

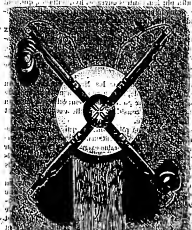

Fig. 160. — Soleil électrique de M. Lontin.

Un seul régulateur peut servir à modérer le courant, non pas d'une seule lampe, mais de plusieurs, de dix par exemple, comme pour cette rampe de dix lampes à spirales de platine représentée par la figure 159.

Ces dix lampes sont dix spirales de fil tendues entre dix paires de bornes de cuivre ; elles sont alimentées par une machine à lumière de force moyenne.

Le fil de platine formant ces spirales a un diamètre de un millimètre, et chaque lampe est constituée par une longueur de vingt-cinq centimètres de fil, ce qui donne deux mètres cinquante centimètres pour la longueur totale de fil employé. Chaque fragment de fil est enroulé en spirale à tours ou spires très-rapprochés les uns des autres, se touchant presque. Avec cette lampe, et au moyen du régulateur, qui empêche la rupture ou la volatilisation du métal, on peut obtenir des effets lumineux des plus remarquables. Chaque spire peut en effet donner une lumière dont l'intensité variera de la simple veilleuse à l'éclat de plusieurs becs Carcel.

Nous devons constater que l'exposition de M. Lontin est vraiment l'une des plus remarquables, si même elle n'est pas la plus curieuse de l'Exposition des Sciences appliquées à l'Industrie ; il ne nous reste plus qu'à nous rendre compte des avantages que ces appareils producteurs…

L'ÉCLAIRAGE ÉLECTRIQUE

PAR LA PILE TOMMASI.

Le Nature Dec 13 1879

Toute invention nouvelle qui se présente au public, appelle son attention à plusieurs points de vue très différents et souvent contradictoires.

C'est le cas de la pile Tommasi qui fait beaucoup parler d'elle depuis quelque temps et dont le côté *affaires* fait trop négliger, par ses promoteurs, le côté *scientifique* et surtout le côté *pratique*. Aussi est-ce au point de vue scientifique et pratique seulement que nous allons examiner les procédés d'éclairage électrique domestique et public de M. Tommasi, laissant de côté le point de vue *affaires* qui n'est ni de notre ressort, ni de notre compétence.

M. Tommasi emploie comme producteur d'électricité la pile Bunsen à laquelle il apporte quelques modifications de détail plus ou moins heureuses.

Prenons pour type, une batterie composée de 16 éléments Tommasi devant faire fonctionner une lampe à incandescence de charbon de 15 becs de gaz brûlant chacun 140 litres à l'heure, chiffres donnés dans la notice qui nous a été remise par la Société lorsque nous sommes allé voir les expériences et sur lesquels il y a lieu de faire quelques réserves.

Chaque élément de la pile Tommasi se compose d'un vase en terre renfermant un cylindre de zinc creux qui lui est soudé par un enduit, pour préserver la surface extérieure du zinc de l'attaque de l'eau acidulée dans laquelle il plonge.

Les vases poreux placés au milieu du vase extérieur sont *hermétiquement fermés*; émaillés dans leur partie inférieure qui contient de l'acide azotique en quantité suffisante pour durer *dix* jours, ils sont poreux dans la partie supérieure qui se trouve en regard du zinc. Les charbons demi-cylindriques sont placés dans le vase poreux à la même hauteur que les zincs dans le vase extérieur. Lorsque la pile est au repos, les charbons ne sont pas plongés dans l'acide nitrique. Pour mettre la pile en activité, on fait descendre dans la partie inférieure des vases poreux, des demi-cylindres de porcelaine dont le volume égale celui du charbon, ils font alors remonter le niveau de l'acide azotique qui vient baigner les charbons.

L'eau acidulée … des vases extérieurs, a une circulation continue à l'aide de syphons convenablement disposés qui les fait communiquer entre eux.

L'invention de M. Tommasi dans cette disposition nouvelle de la pile Bunsen, se réduit donc à préserver la surface extérieure du zinc, idée qui n'est pas neuve, et à boucher hermétiquement le vase poreux pour empêcher le dégagement des vapeurs nitreuses si désagréables et si dangereuses.

Ici la critique est par trop facile au point de vue scientifique. La pile Bunsen *doit* dégager des vapeurs nitreuses pour fonctionner, puisque l'acide nitrique qui joue le rôle de dépolarisant, se transforme en acide hypoazotique pour effectuer cette dépolarisation.

Il faut donc, ou bien que l'acide nitrique soit inerte dans la pile et alors sa présence est inutile, ou bien que l'acide hypoazotique produit se dégage par les pores des vases, et c'est en effet ce qui arrive lorsque l'acide azotique a absorbé tout ce qu'il peut d'acide hypoazotique. Dans la pile Bunsen ordinaire, on laisse échapper l'acide hypoazotique dans l'atmosphère, dans la pile Tommasi il doit traverser les vases poreux : c'est mettre un obstacle à son dégagement, mais non un arrêt, obstacle qui nuit à la production de la pile sans lui enlever ses inconvénients.

Nous ne dirons presque rien de la lampe électrique de M. Tommasi, connue des lecteurs de *La Nature* par les appareils analogues dont elle est une copie. Une tige de charbon de 1 millimètre à 2 de diamètre est appuyée contre un disque supérieur en graphite contre lequel elle est poussée par un ressort comme les bougies de voitures. On n'a qu'à se reporter aux appareils de M. Émile Reynier, Werdermann, Ducretet, Trouvé, etc., précédemment décrits. Nous avons remarqué cependant un système ingénieux qui permet de faire passer le courant d'un charbon à l'autre lorsque le premier est usé, dispositif qui constitue la *Lampe-revolver*. Grâce à la circulation de l'acide sulfurique et au renouvellement partiel de l'acide azotique on peut faire marcher pendant dix jours, à raison de quatre heures par jour, une lampe à incandescence dont la lumière, d'après le rapport de M. l'abbé Moigno égale celle de 15 becs de gaz.

Après ces 40 heures de fonctionnement, il faut démonter la pile pour renouveler l'acide nitrique, nettoyer les zincs, les ré… la pile et ainsi de suite chaque fois … heures. Au point de vue pratique, … nous paraît impossible, et en admettant même les chiffres extrêmes de la notice, nous croyons peu au succès de la pile Tommasi en dehors de quelques applications dans les laboratoires où les manipulations d'acides sont choses fort secondaires.

Nous nous permettrons donc de différer d'avis avec M. l'abbé Moigno lorsqu'il affirme que la lampe Tommasi *brûle sans oxygène et jusque dans le vide* et de différer d'avis avec M. Paul Giffard, — qu'il ne faut pas confondre avec M. Henry Giffard, l'éminent ingénieur universellement connu, — lorsqu'il affirme que la pile Tommasi, donne la solution tant cherchée de *l'éclairage domestique dans toutes les applications possibles.*

Malgré ces affirmations, nous le répétons, la pile économique pratique et domestique reste encore à trouver. Personne plus que M. Émile Reynier n'était intéressé à la solution d'une question qui aurait ouvert à ses lampes un si grand débouché. M. Émile Reynier a essayé toutes les piles connues dont l'application pouvait donner quelques résultats et voici sa conclusion de ses expériences :

« Une pile aussi énergique que la pile Bunsen, aussi économique que la pile Thomson et aussi commode qu'une pile rotative bien agencée, serait encore loin de pouvoir convenir à l'éclairage courant. »

« *Ce n'est donc pas parmi les piles hydro-électriques aujourd'hui connues que se trouve la solution d'un électro-moteur domestique applicable aux lampes électriques actuelles.* »

La pile perpétuelle de M. Tommasi n'a rien changé à ce jugement : le champ reste donc ouvert aux inventeurs.

E. Hospitalier,

Ingénieur des Arts et Manufactures

84

from works Nos. 1 and 3. Whether this arises from the withdrawal of the tar at the end of the hydraulic main, or from other causes, I am not prepared to say, but I may state that a general impression prevails at the works that the illuminating power of the gas has been greater since the adoption of the new plan.

With regard to the remaining figures in the table, the only facts worthy of note appear to be that samples of tar were met with containing as high an amount as 13 per cent. of light naphtha, and that as much as 7·5 per cent. was found in ordinary condenser tar. As these figures were obtained from the analyses of samples taken in comparatively warm weather, it is probable that they represent minimum quantities, and that during the winter months the percentages of light hydrocarbons would be found considerably higher.

In my next article I shall endeavour to show what is the absolute light-giving value of the light hydrocarbons to the gas manufacturer when retained in the gas, the estimate being based on the percentage of naphtha found in the stock tars.

ON THE USE OF THE RADIOMETER AS A PHOTOMETER.

35

By Mr. ALEXANDER PEDLER, F.C.S. (London and Berlin), F.I.C., Professor of Chemistry, Presidency College, Calcutta.

In a paper "On the Mechanical Action of Light," by Mr. Crookes,* written about four years ago, and which gave a sort of summary of the results obtained with the radiometer, a few photometrical experiments with the instrument are given, and from them it is concluded that the radiometer is a perfect photometer. The author says: "By this means photometry becomes much simplified; flames the most diverse may readily be compared between themselves, or with other sources of light. A standard candle can now be defined as one which, at *x* inches off, causes the radiometer to perform *y* revolutions per minute (the values of *x* and *y* having previously been determined by comparison with some ascertained standard); and the statement that a gas-flame is equal to so many candles may, with more accuracy, be replaced by saying that it produces so many revolutions." This conclusion being of great practical importance, and as the experiments on which it was based were very few in number, it appeared to be advisable that they should be, if possible, confirmed by a more extended series of observations.

It being part of my regular work to test the illuminating power of the Calcutta gas, I made a series of observations with the radiometer, comparing it with a standard gas-flame, whilst I was at the same time determining the illuminating power by the ordinary photometric method, as prescribed by the London Gas Referees. My first results were embodied in a note read before the Asiatic Society of Bengal, and published in their Proceedings for August, 1876. The conclusions at which I arrived were not very favourable to the use of the radiometer as a photometer, and one great cause of the discrepancies of my results was apparently to be found in the friction of the instrument. In the paper referred to I say: "It will be seen that these results agree very closely with those calculated according to the law of inverse squares; that is to say, the number of revolutions of the radiometer will be inversely proportional to the square of the distance from the source of light. But it will also be noticed that there is one marked exception to the rule, and that is at a distance of 10 inches from the gas-flame, where the rapidity of revolution is great. Here the actual number of quarter revolutions amounted to 59·36 per minute, whilst theoretically they should have been 90. Evidently when the radiometer is rotating rapidly there must be an immense increase in the friction, so as to reduce the rotation by one-third of the whole amount. There are also indications that when the radiometer is rotating very slowly, there is a considerable disturbance from the theoretical rate of revolution, probably showing that friction has much influence both when the rotation is slow and rapid." My general conclusions on Mr. Crookes's proposal to use the radiometer as a photometer were summed up in the following paragraph in the same paper:—"It is, I think, evident, from these experiments, that it would be impossible to say that because a radiometer rotated 16 times as rapidly with one flame as it did with another, the former flame possessed 16 times the illuminating power of the latter; for it must be seen that in working with either a very high or a very low rate of revolution, there appears to be considerable disturbance due to the friction of the instrument. It is, I believe, possible and even probable that much better results will be obtained by working the radiometer always to a fixed number of revolutions (say about 30 or 40 quarter revolutions per minute), and by altering the distance of the flame until such rapidity is obtained; in this way the friction of the instrument would be reduced to a constant quantity, and the comparative luminosities would be judged by the squares of the distances."

In the hope of proving the feasibility of this method of procedure, I have carried on a series of experiments with the Calcutta gas for more than two years, testing the illuminating power simultaneously by the ordinary photometric method and by the radiometer. The method of procedure was very simple. The instrument used was an ordinary radiometer with four aluminium vanes blackened on one side. The vanes rotate on a steel point, which is supported in the usual glass cup. The glass globe of the radiometer is about 6 centimètres in diameter, and it stands about 18 centimètres from the table. The radiometer was placed on a table which was graduated in centimètres, the zero point of the scale being made the centre of the radiometer. A standard Argand burner was so arranged that the centre of the flame was as nearly as possible at the same height as the vanes of the radiometer, and by means of a test meter exactly 5 cubic feet of gas per hour were burned in the jet. The burner was then moved towards or away from the radiometer until the vanes made exactly 15 whole revolutions or 60 quarter revolutions per minute. This number was selected as being most convenient, for by having a clock in the room audibly beating seconds, it was easy to see whether the rapidity of rotation was correct or not. The radiometer having then attained a constant speed of 60 quarter revolutions per minute, the distance of the centre of the flame from the central pivot of the radiometer was noted. No extraneous light was allowed to reach the radiometer, for all other flames which were burning in the room at the time of determination were either enclosed in the photometer or their light was screened off in some similar way. At the same time, and from the same supply-pipe, the illuminating power of the gas was determined by the photometrical process adopted by the London Gas Referees. In this process the illuminating power, as is well known, is corrected both for the temperature and pressure of the gas at the time of the experiment, the standard of 60° Fahr. and 30 inches pressure being adopted. In this way a large number of values were obtained for this particular radiometer, the experiment for each day showing that a certain distance of the standard flame from the instrument was equal to an illuminating power of so many candles.

To compare each day's experiment with others, I calculated from the numbers obtained what should have been the distance of the standard light from the radiometer if the gas had possessed an illuminating power of 12 candles. The calculation is, of course, a simple one, the distances being directly proportional to the square roots of the illuminating powers. Very considerable variations were, however, found in the numbers thus calculated; but I still persevered with the experiments until I had obtained between 250 and 300 results, which I thought would be sufficient to show the causes of these variations. I did not, of course, expect to obtain a perfectly exact agreement of the results of the photometer with the radiometer, for there is no doubt that the photometric method, though much improved, still does not give absolutely reliable results. This is inherent in the method itself, and it can scarcely be said to be capable of giving results nearer than *plus* or *minus* half a candle. In the second place, the colour of a gas-flame is known to vary somewhat, being sometimes comparatively white, but generally degenerating into a very decided yellow, and Mr. Crookes* has pointed out that different coloured rays have different actions on the radiometer. At first I was inclined to ascribe the differences I obtained to the above two causes; but as my experiments multiplied, and especially as the seasons here changed from the so-called cold weather to the hot weather and rains, it appeared that another and more serious cause affected the results. It appears clearly from my experiments that at the comparatively high temperatures which obtain here during the hot-weather months, the radiometer which I have used is very much less sensitive than at lower temperatures.

In all the experiments which I have made, I have recorded the atmospheric temperature and pressure; but, so far as I can see, it is practically impossible that the slight differences of atmospheric pressure which obtain here can have any effect on the rotation of a radiometer. No attempt has, therefore, been made to connect the changes in the sensitiveness of the radiometer with changes of atmospheric pressure. The readings of temperature are, however, important, for it is clear that, with every change of temperature, there will be an alteration in the tension of the residual gas in the radiometer. It is unfortunate that, working in a comparatively small room, as I have had to do, with sometimes three or four gas-jets burning, as well as the standard candles, it has been practically impossible to keep the atmospheric temperature constant. I have usually read the thermometer immediately on making the determination with the radiometer; but as the temperature was constantly though gradually rising, the exact temperature of the experiment is a little doubtful, for the temperature of the air and of the radiometer during the actual experiments may have varied by a degree or more from the observed temperature. It is clear also that the action of the light on the radiometer will be to raise its temperature, and this will be another disturbing cause which it is impossible to overcome. To eliminate any such slight doubt as the actual temperature at which the experiments have been made in the table below, I have grouped the experiments for every five degrees (Fahrenheit) of temperature. Starting with the lowest temperature which we have here of about 66°, the first group will be from 66° to 70°, the second from 71° to 75°, the third from 76° to 80°, and so on:—

Temperature of Air at Time of Experiment. — Deg. Fahr.	Number of Observations made between these Temperatures.	Calculated Distance of Standard Flame of 12-candle Power from the Radiometer in order to produce 60 Quarter Revolutions per Minute.	Differences.
66 to 70	8	54·5 centimètres.	—
71 „ 75	29	51·7 „ „	2·8 centimètres.
76 „ 80	25	49·5 „ „	2·2 „ „
81 „ 85	51	47·8 „ „	1·7 „ „
86 „ 90	91	46·6 „ „	1·2 „ „
91 „ 95	56	43·1 „ „	3·5 „ „
96 „ 100	8	39·8 „ „	3·3 „ „

It will, I think, be clearly seen from these numbers that the radiometer used in these experiments is much more sensitive at low than at high temperatures. At temperatures of 71° to 75° Fahr., with 12 candle power gas, to obtain 15 rotations of the radiometer per minute, the gas-flame is placed at 51·7 centimètres distance; but with the same amount of light to obtain the same velocity of rotation at a temperature of from 96° to 100° Fahr., it is necessary to

The communication "On the Use of the Radiometer as a Photometer," by Professor Pedler, F.C.S., of Calcutta—which the kindness of Dr. Frankland enables us to publish in another part of the present number of the JOURNAL—is the most exposition which has yet appeared of the exact relations of Professor Crookes's discovery to the modern practice of photometry. We need not repeat in detail the great expectations which were formed at one time, with much apparent reason, respecting the possible value, as a means of measuring light, of an instrument which was supposed to be moved by the action of light itself, and whose rate of motion seemed to depend directly and solely on the intensity of the light to which it was exposed. In this discovery of a motive power in light the germ of the most perfect of all possible photometers seemed to lie, only waiting the slight additions necessary to embody the principle in a workable form. But it is now evident from Professor Pedler's account of his experiments in this direction, that there are causes of disturbance and error in the radiometer itself and in the conditions under which it must be used as a working implement, which render its indications too irregular to be trusted as a measurer of light. The effect of temperature on the extremely rare medium which fills the radiometer-bulb is shown by Professor Pedler to be almost as abnormal as the functions of the instrument itself, and it would be impossible to rely, however tentatively, upon the indications of any particular radiometer until the constants due to its own structural peculiarities had been determined, with some accuracy, by long and difficult experiment. The net result of Professor Pedler's labours, which were most carefully directed to the avoidance of all prejudice and preventible error, seems to be that when the peculiar requirements of a radiometer-photometer are most scrupulously observed, its records are at best only to be taken as approximately correct, when compared with the candle-photometer. Such a conclusion must be held as entirely condemnatory of the apparatus in question. We know that the ordinary photometrical method gives results only approximately true, and what is wanted in its place is not another method of similarly incomplete character, but one which shall be positive, and free from the risk of error which must always be present when the personality of the observer plays such an important part in the determination of the result, as it does in the present system. The radiometer appeared to offer a possibility of immunity from this personal element, and if this could have been secured without counterbalancing dangers a great advance would have been made in the exact measurement of the power of light. But we must now cease to expect that this desirable end will be attained by the agency of the radiometer, for although it is perfectly mechanical in its action, it has been shown to possess a multiplicity of defects, apparently inherent and insurmountable, which render its use as a photometer chimerical.

Scientific American Supplement Nov. 18, 1880

THE FOURTH STATE OF MATTER—A REFUTATION.

IT may interest the readers of *Science* to know the opinion held in Germany respecting those phenomena which led Mr. W. Crookes to believe he had discovered a fourth state of matter. For this purpose we have translated and abridged an article by Dr. J. Puluj, the well known scientist of Vienna, published in the *Chemiker Zeitung*:

According to Mr. Puluj, the beautiful experiments of W. Hittorf, published in 1869, under the title "Electrical Conductibility of Gases," have received too little attention from our scientists, it may be, on account of the modest title. The scientific labors of Goldstein, and some interesting researches of Hertinger and Urbanitzky have met with the same fate. W. Crookes, the renowned English chemist, to whom the writings of the above-named gentlemen were evidently unknown, made similar experiments, the results of which did not differ essentially from those of Mr. Hittorf. His conclusions were, however, entirely new; he declared that his experiments proved a fourth state of matter.

THE ELECTRIC DISCHARGE IN RAREFIED GASES.

SEVERAL Continental *savants* are engaged just now in controverting the claim of Mr. Crookes to the discovery of a fourth state of matter, and otherwise prosecuting the same line of research. The well-known electrician, Dr. Gintl, of Prague, one of the original inventors of the duplex system of transmission, has arrived at the conclusion that the light seen at the negative poles in Crookes's rarefied tubes is due to molecules of the metallic electrode torn off by the discharge, an opinion which is sustained by Dr. Puluj, of Vienna. Articles interposed in the molecular stream have been found to acquire a coating of the atoms, and if this coating does not take place in the case of an aluminium pole (as has been pointed out by a supporter of Mr. Crookes), it may be due to the fact, elicited by some experiments of Herr E. Wiedemann, that aluminium poles are least liable to disaggregation under the electric discharge. Dr. Puluj, we learn from our contemporary *l'Electricité*, has contrived a pretty electric light from the negative discharge in a vacuum tube from a Ruhmkorff coil capable of giving a spark of ten centimetres in length. In this device the metallic dust wrenched from the metal pole is concentrated upon a positive pole of carbon which reaches a red heat, but suffers no loss of matter.

The latest published researches on this interesting subject are those of M. Righi, recently communicated to the French Academy of Sciences. His results are as follows:—

1. If, while we produce by means of a Ruhmkorff coil the illumination of a Crookes vacuum tube (for example, one of those in which the negative electrode is cylindrical or spherical), we approach to the glass a conductor connected to the negative electrode, and if at the same time, by means of a magnet, we cause the discharge to bend itself towards the same side of the tube, we shall observe a dark spot produce itself in the midst of the green fluorescence at the part where the glass is negatively charged. It would appear, therefore, that the glass becomes luminous at the point where it acts like a positive electrode.

This results equally from the two following experiments:—

2. Let us insulate one of these tubes by means of long silk threads and approach to the wall a ball communicating with the positive conductor of a Holtz machine. The electrodes of the tube emit positive electricity into the air, and negative is emitted by a point applied to the conductor. The green fluorescence appears upon the electrified wall of the tube, which acts as the positive electrode in the interior discharge.

3. M. Righi has approached the same ball, or a metallic point to the wall, or a little cylindrical Geissler tube containing sulphate of calcium, or phosphorescent strontium. The powder becomes strongly luminous, opposite the ball, if it is negative, and very feebly luminous if it is positive. If the ball, being negative, is placed near the extremity of the tube in such a way that one of the electrodes is between the ball and powder, we distinctly observe the shadow of the electrode project itself upon the powder. We thus obtain with an ordinary Geissler tube one of the striæ phenomena described by Mr. Crookes.

4. The pale light, azure or violet, that is seen in all the tubes of Crookes is strongly influenced by the hand or by conductors brought near the tube. M. Righi has connected the electrodes of the tube with the conductors of the Holtz machine (without condensers), and has approached insulated balls connected with the two electrodes. Under these circumstances he always finds that the light due to the discharge is attracted by the positive ball, and repelled by the negative one, that is to say, the discharge acts like a body negatively electrified. He has observed this phenomenon, although with less evidence, in Geissler tubes, and particularly in the little tubes containing nitrogen or carbonic acid. Ordinarily the hand repels the discharge, perhaps, because it charges itself under the influence of the tube. See the next experiment.

5. Mr. Crookes has shown that all insulated conductors introduced into one of the tubes charge themselves positively. The following experiment of M. Righi explains this phenomenon.

If, while the current from a Holtz machine is made to pass in a long Crookes tube, we approach to it perpendicularly by one of its electrodes, a small Geissler tube, the other electrode of which is held in the hand, we see in the latter tube a discharge directed from the long tube to the hand. If the potential of the positive conductor is reduced to zero, the little tube becomes dark; but if, on the contrary, we touch the negative conductor, the little tube is traversed by the discharge. It seems, then, that the long tube almost throughout has a potential little different from that of the positive electrode, and that near the negative electrode there occurs a very great fall of potential. It is, therefore, probable that during the discharge the negative electrode becomes heated much more than the positive electrode.

6. This is demonstrated by M. Righi by the following experiment:—The discharge from an induction coil is sent through the electric radiometer; holding the latter in such a position that the mill cannot turn. The discharge is then interrupted, and the apparatus brought back to its normal position, taking care to avoid turning the mill by shocks in the ordinary way or even giving it a negative rotation. Very soon the mill will begin to turn almost with the same swiftness and in the same direction as if the apparatus was still traversed by the discharge. The cause which makes the mill turn is apparently the heat developed when the rolls act as negative electrodes.

According to this experiment, the cause of the mechanical actions proper to the negative electrode are the same as in the radiometer. The electric force of the negative electrode upon the molecules which rush from it charged with negative electricity ought to tend to direct them normally to the surface of the same electrode. When these molecules collide with the glass they discharge themselves upon it, and the glass becomes luminous (see experiment No. 1). In fact, it is often noticeable that discharges pass from the positive electrode to the fluorescent portions of the glass.—*Electrician.*

being kept touching each other; also of the special use of carbon as a convenient resistance for electric light circuits."

The various details of the invention are particularly described with reference to the drawings annexed to the specification.

TRIPLICATE MARSEILLES AND ALGIERS CABLE.

The ss. "Dacia," Capt. Hayward, belonging to the India Rubber, Gutta Percha, and Telegraph Works Company, left Greenhithe on Sunday, the 13th instant, for the Mediterranean to lay a third cable for the French Government between Marseilles and Algiers. The expedition is under the charge of Mr. R. K. Gray, engineer to the India Rubber Company. We have already given particulars of the cable as regards length and type (see *Electrician*, July 31). The insulation resistance is about 700 megohms at 75° Fahrenheit. The ship carries two electric lights, the current being supplied by two Gramme machines worked by two separate engines. These lights light the deck for paying out, picking up and sounding. The lamps have an ingenious hand adjustment. Regnier lamps are carried for lighting the tanks. A sounding wire apparatus, with improved self-adjusting break, is fixed permanently at the taffrail, on the starboard side, the cable stern sheave being on the port side. The machine is driven by a small engine fixed close to it, and connected by driving wheels with vulcanised india rubber tires. The ship carries a buoy containing tanks filled with gas and carrying a well-designed lamp. Electric signals are fitted from bow, stern, and bridge to the engine room and helm. These have been in use in the ship for several years, and answer very well indeed. A system of electric bells between all the cabins, chart rooms, deck-houses and saloon, to the stewards' pantry, is fitted; and altogether the arrangements show that all appliances are being tried that will facilitate the work and thus reduce its cost. Mr. R. K. Gray is, as we have stated, engineer in charge; Mr. E. M. Webb is chief electrician; and there is an excellent staff of assistants, including Mr. Page, who has charge of the electric lighting apparatus, Mr. J. Gray, Mr. C. Gray, Mr. Jones, and Mr. Bosse. Several gentlemen more or less connected with the company or with telegraphy have, through the courtesy of the directors, received passages as visitors, including Mr. Tyler (the secretary to the company), Mr. Foster (son of the late Mr. Le Neve Foster, formerly the much respected secretary to the Society of Arts), Mr. Robinson (secretary to the West Coast of America Telegraph Company), Mr. Alfred Niaudet (the well-known French electrician), Mr. Jackson, and Mr. H. L. Webb. It is expected that the work will be completed and the "Dacia" back at Silvertown in about six weeks, and she will soon afterwards start with the "International," to lay the new Mexican cable. The steamer "Newfield" will start in about a fortnight from Silvertown to lay the several cables for the Canadian Government which are being made at Silvertown. Mr. King, formerly engineer to the Western and Brazilian Telegraph Company, has charge of this work.

THE ELECTRIC DISCHARGE IN RAREFIED GASES.

Several continental *savants* are engaged just now in controverting the claim of Mr. Crookes to the discovery of a fourth state of matter, and otherwise prosecuting the same line of research. The well-known electrician, Dr. Gintl, of Prague, one of the original inventors of the duplex system of transmission, has arrived at the conclusion that the light seen at the negative poles in Crookes's rarefied tubes is due to molecules of the metallic electrode torn off by the discharge, an opinion which is sustained by Dr. Puluj, of Vienna. Scientific Am. Dec. 8 7

An important improvement in the Sprengel air pump was described by Prof. O. N. Rood, of Columbia College. After cutting off certain sources of leakage into the apparatus by means of mercury traps, he obtained a vacuum of one-sixty millionth of air atmosphere. Still finer results were obtained after the adoption of devices for withdrawing the moisture contained in the mercury used. In conclusion, Prof. Rood said that he had obtained vacua as high as the ninety-four-millionth of an atmosphere in some of his experiments, and in one had gone as high as one one-hundred-and-ten-millionth. There was no reason why higher results even than these should not be obtained, as it was merely a question of making the pump perfectly tight and excluding moisture. Prof. Crookes, of London, who has experimented in this direction, has reported his highest result as one-twenty-millionth of an atmosphere, and in France a distinguished experimentalist had recorded a vacuum of one-seventeen millionth.

A METHOD FOR PRODUCING THE LIGHT-PHENOMENON OF GEISSLERS' TUBES.—L. Weber.—A U-tube whose limbs are about 770 millimetres in length is filled with mercury, inverted and placed with its limbs in two capsules filled with mercury and connected with the ends of an induction-coil.—*Wiedeman*

WORLD OF SCIENCE AND ART.

FRIDAY, APRIL 7, 1882.

ELECTRIC INCANDESCENT LAMPS.

JUDGING from the numbers of incandescent lamps which are now made every week, it is evident there must either be a very great demand for them or they must be very short-lived, for, if rumour is to be credited, one factory alone is turning them out at the rate of several thousands a week. There are at present five competing patterns, which differ from one another only in details, though some of them are very important, while others are mere matters of choice. From time to time we have given particulars of the various patents which have been taken out in connection with the "bridges" or threads of carbon which form the incandescent medium, and the method of preparing which seems to be the only real point of novelty in connection with the lamps. The early experimenters speedily discovered that even with a so-called perfect vacuum the carbon filament rapidly gave out, owing to the gases occluded in the pores of the carbon, and whilst some sought for special fibres, others endeavoured to so prepare the better-known materials as to overcome this difficulty. Hence, while Edison has, according to rumour, scoured the world and settled upon bamboo fibre, others have contented themselves with more easily-obtained materials, and have endeavoured to prepare what is needed by treating ordinary substances in such a manner as to render them practically homogeneous. Without attempting to give the dimensions of the outer shells of the lamps, which are really of no particular moment, it will suffice to say that they all consist of oval or globular glass envelopes, with more or less elongated stems, and a tubulure at the other end which is left for connecting with the vacuum-pump. The carbon thread, mounted with its wires in the stem-block, is passed into the shell and hermetically sealed by melting the glass around it, and the "lamp" is then placed in the vacuum-pump and submitted to the special treatment which the rival inventors or patentees favour. In Edison's case the thread is raised by degrees to a high state of incandescence while in the "pump," cooling being allowed after each passage of the current. By this means the occluded gases are believed to be eliminated, and certainly the fibres are submitted to a greater trial than they will experience in their future life as lamps. Of course, many of them fail, but the process secures the survival of the fittest, for it is only those which stand the test that are finally sealed up as practically perfect. Other inventors prefer to submit their carbon threads to a high heat in the presence of hydrocarbons, by which means they fill up the pores of the fibre with carbonaceous matter, and make the threads nearly or, it may be, perfectly homogeneous. In any case the final exhaustion is carried as far as possible before the lamp is sealed and passed as ready for use. At the Crystal Palace five different patterns are shown: the Swan (the earliest), Edison's, Maxim's, Lane-Fox's, and the British, and in appearance there is little to choose between them. The real test of superiority is, of course, durability, and of that we have no particulars, save that while at first the life of the lamps was reckoned only in hundreds of hours, it is now reckoned by thousands. Just as in the arc lights, the positive carbon wastes more rapidly than the negative, so in the incandescent threads it is found that there is a transference of carbon from one end of the bridge to the other, and although in the newer devices this defect has been partially remedied by making the thread thicker at the negative end than at the positive, it is obvious that it practically determines the life of the thread, which sooner or later must give out. We hear of threads lasting 4,000 hours, and even longer, which, for practical purposes, means a year of lighting without requiring new lamps; but we imagine that in making an estimate it would be preferable to reckon the life of a lamp at 2,000 hours, which will probably cover contingencies. Besides the carbon thread itself, an important point is the means of connecting it with the wires, and here we find the chief divergence between the different systems; for while Edison prefers, or, at any rate, uses platinum junctions coated with copper, Lane-Fox coats the ends of his filaments with platinum, and dips them into globules of mercury. Maxim's, Swan's, and the British, all use platinum connections slightly varied. For the filament itself, Lane-Fox uses the fibre familiar to housekeepers as bass-broom, the British Company use cocoanut fibre, Maxim and Swan prefer paper, cardboard, or cotton, and Edison, as mentioned above, bamboo. The latter, in fact, professes to have tried all sorts of substances, and to have found in certain species of bamboo just the kind of fibre he requires, both for uniformity of substance and for the facility with which it lends itself to the necessary manipulations. On page 462, Vol. XXXIV., we illustrated and described Edison's latest method of making and arranging incandescent lamps, and it will be sufficient to say here that the bamboo canes are first cut into lengths, then split through the centre, and each half further divided into three. The hard flinty shell is then removed, and the pieces planed down to uniform thickness, when they are placed between metal blocks and subjected to forcible compression, leaving the pieces as fine threads of bamboo with thick ends. They are then ready for the most important stage in their preparation. This consists in bending them to the required shape by forcing them into grooves in a nickel plate, which is then covered by another plate of the same metal, and the two being clamped tightly together, are raised to a red heat in a furnace. The filaments are thus carbonised, and are attached to the platinum wires in the glass foot or stopper of the lamp (see p. 462, Vol. XXXIV.) by a copper film deposited by electrolysis. The foot being blown into the lamp, the latter is put in the pump, and while the exhaustion is being carried on a current is sent through the bridge of bamboo fibre, which is allowed to cool down several times, while it is raised by degrees to the highest state of incandescence. It is believed that by this means the occluded gases are completely eliminated, but other researches have shown that it is extremely doubtful whether any natural fibre or other form of carbon can be altogether freed from hydrogen, and Mr. Edison acknowledges that, in the present state of the art, it is impossible to construct a lamp which shall have an indefinite duration so far as the carbon thread is concerned. The vacuum in the lamps is produced with ease by means of a modification of Sprengel's pump, a tube being left projecting from the top of the shell, which is connected to the pump-tube. The required vacuum having been produced, the tube is sealed near the joint with the pump, and the lamp being thus separated, the final closure of the shell is made in the form of a bulb fused on the end of the tube, which in the finished state is little more than a projection from the surface of the shell. The lamps hitherto shown by Edison are pear-shaped, but other forms have been made, that most liked by the inventor being a cylinder with rounded ends. In all, however, the finishing or connecting terminal is a screwed piece in which the platinum wires are secured respectively to a screw and a cone in thin brass (the latest are of thin copper), which are insulated from each other by plaster of Paris. The socket, which has the "lead" and return similarly connected to a cone and a female screw, thus makes perfect metallic contact with the lamp as soon as the latter is screwed home. The details of this arrangement have been modified in some specimens, but in principle they are the same. The large-sized lamps have a resistance when hot, of 130 or 140 ohms; the smaller or 8-candle half-lamps, as they are termed, have a resistance of about 80 ohms.

The description above given of the manufacture of the carbon filaments applies with some alteration of detail to all the lamps mentioned; but all the inventors have not been so successful in devising an easy means of securing perfect connection with the main lead and return. Edison uses a filament with a plain bend, Maxim bends it twice on itself so that it represents the letter M, and Swan, as we have previously shown, uses either plain loops or coils. The Maxim lamp is fitted into a socket containing two insulated springs as terminals to the conducting wires, so that perfect contact is maintained by their pressure. These details, which are really of considerable importance, will no doubt be improved; but at present the plan adopted by Mr. Edison is by a long way the most simple as well as efficient. The arrangements for turning out a lamp are practically the same in principle and can be readily understood. The tap, which resembles nothing so much as a gas-tap, in one position is in contact with the lead, lamp, and return, and in the other with only the lead and return, so that no current passes through the lamp when the tap is turned sufficiently to break the circuit with the lamp. Edison uses a split cone, which is, by means of a quick screw-thread on the tap, drawn into connection with two metal blocks, to which the wires are secured. In these simpler arrangements it will be understood that the light given by the lamp depends on the machine generating the current; there is no means of reducing it by turning the tap, which, as before explained, either makes or breaks circuit; but amongst Mr. Edison's devices there is one by means of which the amount of light can be regulated within certain limits. That he accomplishes by means of a rheostat composed of a number of vertical rods of carbon, resembling an elongated lantern-pinion. By turning the base of the box the resistance offered to the passage of the current can be increased or diminished, and within those limits the intensity of the incandescence of the carbon filament can be regulated. The display of incandescent lamps at the Crystal Palace, the steadiness which is their peculiar property, as compared with the arc lights, and the facility with which they lend themselves to all purposes of domestic lighting, have made them the popular favourites; and, we understand, that one factory is selling them at the rate of several thousands a week. The duration of any of these lamps is determined practically by the durability of the carbon filament, though occasionally the glass envelope fractures; but the problem to be solved is the possibility of so preparing the threads and so shaping them that they may have an indefinite life, for it is

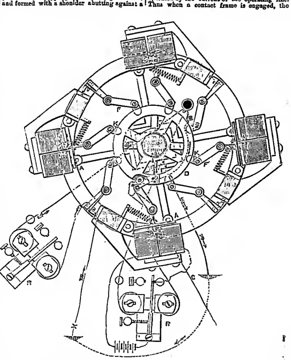
clear that if any serious expense is incurred in replacing broken or worn-out lamps, the incandescent system, already more expensive, from the photometric point of view, than the arc lights, will be severely handicapped. That many inventors are turning their attention to the production of superior carbons, our columns testify, and probably in some such direction as that taken by Mr. Crookes (see p. 247, Vol. XXXIV.), the greatest measure of success will be attained.

TELEPHONE EXCHANGE APPARATUS.

THE Telephone Exchanges have scarcely done more than elaborate, and make fairly complete, the systems of switching for use in central stations, before an ingenious inventor comes forward and provides an arrangement by which any subscriber can connect his telephone with that of any other member of the exchange by means of an automatic instrument in the central office, thus dispensing with the services of an attendant. This apparatus has been patented by Mr. T. A. Connolly, of Washington, and has been recently patented in this country as well as elsewhere. To give a full idea of the various ways in which the invention can be worked would occupy more space than we can spare, but with the assistance of the annexed engraving we shall probably be enabled to render the principal features clear. The apparatus at the central station is of an upright cylindrical form carried on a base with the binding posts to which the various line wires are attached. The engraving is a horizontal section, showing, as if they were on one plane, the electro-magnets, the pivoted armatures of which are connected to escapements or ratchet and pawl devices, for converting the motions of the armatures into the rotary motion of a ratchet wheel. The magnets are really in separate planes or tiers as we may say; they receive current from the central battery, and normally the circuits are open. The closing of these circuits is effected by means of relays R in the normal circuits of the subscribers' or members' lines; these relays are responsive to the impulses transmitted from the subscribers' stations, hence each pulsation of an armature A is in keeping or correspondence with that of its relay. These relays are polarised, and preferably of the form known as "Siemens'," and are adapted to close the circuit of the magnets when the current which energises the said relay is passing in one direction. The current in the reverse direction may be utilised for signalling purposes without affecting any operation of the central machine. The magnets and their ratchet appliances are employed to effect the rotation of the rings or wheels D, one of which is allotted to each line. In addition to a ring each line possesses a "contact bar" or frame F; these frames are pivoted either inside or outside the ring, or outside of the wheel; they are arranged at regular intervals around the rings, and are parallel with the axis thereof. Each bar traverses the whole series of rings, so that all the rings have a similar relation to each and every frame. A connection of any two lines is effected through the ring of the operating or calling line and the contact bar or frame of the called line; for this purpose each ring is furnished with a coupling or connecting device, which in the arrangement under consideration consists of a "tripper" or toggle lever; this lever, as a ring D rotates, comes in contact with the several frames, and rotates the same on their shafts or bearings; at the same time the tripper or toggle, which is normally tangential or inclined with reference to the periphery of the ring, assumes a different position, that is to say, it straightens out, and if then the movement of the ring is discontinued, the tripper and frame remain in their conjointly assumed positions. The object of moving the frame is to isolate it, so that when engaged by a line no other line can obtain connection with it; for this purpose the conditions are such that in its normal position the outer end or head of the tripper does not project sufficiently far beyond the ring or wheel to touch the frame or contact bar when moved or turned by an engaged tripper or toggle.

A line when not in use, or when employed in effecting connection with another, completes its circuit to earth, or to a common ground or return through its tripper or toggle. When engagement is made with a line, this ground or earth connection is broken by the movement of the tripper under the toggle action of a frame or contact bar, and the circuit is completed through the line in which the frame is located. Speaking more specifically, each ring or wheel consists of two plates or rings of metal separated by an insulating filling; the lower plate is in constant contact with the frame of the central machine which communicates with earth, or return, either through supporting rollers if a hollow ring is used, or through a central shaft if a wheel with spokes is employed.

The tripper or toggle lever consists of a finger pivoted to the upper plate of the ring or wheel, and formed with a shoulder abutting against a stop, which limits its movement in one direction, and against which the tripper is held in impingement when not engaging with a contact frame by an easily yielding spring. A spring tail piece or continuation of the tripper or toggle impinges against a bent metal pin, stud, or block extending upward from the lower plate of the wheel or ring, and travels thereon during a portion of the movement of the tripper on its pivot. Thus the operating line which leads into the upper plate and thence to the tripper or toggle makes ground through the said pin, stud, or block, until in engaging with a contact frame such ground connection or contact is broken by the tail-piece leaving the same, when the circuit is diverted into the contact frame to be thence led to the line thereof. As above stated, the tripper or toggle lies normally in an oblique or tangential position, as shown; its outer end is formed with a slight concavity or recess, by which a contact frame in its path is caught and held in effecting and maintaining engagement therewith. As the tripper passes each unoccupied contact frame, momentary engagement and conjoint movement ensue, and the diversion of the circuit from central ground to the line of the engaged frame follows. The circuit or contact is made with the ring from the line thereof by means of a brush or rubber B in the path of the same line insulated from the main frame. A wire leading from the said brush connects with a binding post or cup to which is led a return wire from the relay of the same line. The main line wire G from a station leads to connections in the central machine, thence to the relay, and from the relay by the return wire to the binding post. This circuitous path is provided in order that the relay of a called or passive line may be cut out, so as to reduce resistance, but principally to prevent such relay from being operated by the current of the operating line. Thus when a contact frame is engaged, the



circuit with its line is made directly from the outer segment to the line without passing through the relay, the latter being in the branch circuit connected permanently with the inner or shorter segment. It has been explained that when a contact frame is swung out to its limit and engaged by a toggle or tripper, the toggle or tripper of another line will pass by without coming into contact therewith, thus preventing disturbance of the communication through the frame of the called line. Engagement, however, with the frame of an operating line is not thus provided against, but such provision is necessary to prevent the operating line from being broken. For this purpose each contact frame is furnished with an arm K supporting an anti-friction roller, which rides on the periphery of the insulated filling of the ring of the same line. A cam recess in the said filling adjacent to the tripper receives the said roller when the ring is home, but as the latter begins to move the roller is pressed outward to the periphery of the insulated filling. By this

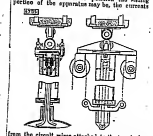
4755. IMPROVEMENTS IN ELECTRIC LAMPS AND APPARATUS CONNECTED THEREWITH, *J. A. Berly and J. D. Hulett*.—18th November, 1880. 6*d*.

This invention relates to an apparatus for suspending electric lamps so as to enable the said lamps to be pulled down, detached, &c., to be regulated or attended to, and pushed back into their former position whilst alight. Fig. 1 is an elevation, and Fig. 2 a longitudinal section of the apparatus. In whatever position the sliding portion of the apparatus may be, the currents



from the circuit wires attached to the terminals N will be conveyed to the strips of metal J and collected by the friction pieces G, from which, through bolts, F, to which they are electrically connected, the second currents will be conveyed to the lamps by means of the conducting wires attached to the heads of the bolts F. The whole apparatus being enclosed, is free from dust and not liable to be damaged, which ensures regularity of working.

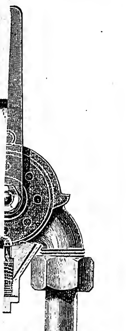
Industrial News, Aug. 1881.

THE SUN ELECTRIC LAMP.

La lampe soleil, as it is termed, is a new French electric lamp of considerable promise and some novelty. The light is formed by boring two converging holes into a small block or brick of marble, and inserting into these two carbon rods. The rods are separated at their points by a partition of the marble, and they nearly penetrate through the block. Their upper ends are connected to the dynamo-electric machine, and the current in traversing the wall of marble between their points makes it white hot. The carbons are slowly consumed, the gas escaping from the bore-holes, which are wider than the rods, and they are fed to the arc by their own gravity. The light is admitted by the bottom of the brick, which becomes calcined, and is of a mellow lustre like the sunshine. The cost is said to be only a sou per hour, the carbons consuming at the rate of a centimetre in that time. Already *la lampe soleil* has been introduced into several places in Paris, including the mayor's residence, and it will form a feature of the forthcoming exhibition. It is the invention of MM. Clerac and Bureau; but it reminds us of the electro-calcic lamp patented by Mr. Wentworth L. Scott in 1878, wherein a block of lime or other earth is interposed between the electrodes of the arc. Mr. Scott did not arrange his apparatus like the sun lamp; but his intention was, we understand, to heat a piece of lime white hot by the current, just as it is heated by the mingling gases in the Drummond limelight.—*Engineering*.

90

lin. by 3-16ths. As to filling them, I am afraid that with the very limited experience I have had with reeds, I should utterly spoil them by attempt-

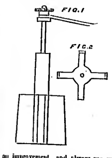


enabled to say whether he knows it or not; I fancy, however, that it is new, although in looking through the back volumes of "ours" for articles on reeds I came across the description of a similar instrument in principle, under the heading of "Automatic Reed Organ," and the "Melophon" is decidedly a modification of the same thing. I would ask "Saul" if he thinks accordion reeds would do for this instrument? I have never seen any myself, so cannot tell. Having written over 350ft. of music from "Les Huguenots," "Faust," "Tannhauser," and other operas, I should much like to put in better reeds. At present I have in the original ones, but the tone is anything but satisfactory. The execution of the music by the machine is all that could be desired, although, of course, there is no expression.—Melos.

[11135.]—Medical Coil.—The form of Fuller cell I employed for my small coil, in which a circular porous pot was used, was modified by using a zinc of cruciform section. To show this more clearly, I inclose sketch, showing elevation and plan of zinc element. The original form was a circular zinc of conical shape only, and, for good reasons, could not be as large as the star-shaped zinc. I found

FIG.1

FIG.2



this an improvement, and always use such in a battery of circular form. As you are doubtless aware, the porous pot also contains a quantity of mercury. This rises readily enough for a given distance; after that it cannot be depended on; therefore the stem connecting the arms with the copper wire was Brunswick-blacked or covered with pitch. The copper wire stem is cast in. When using the plate-form of zinc element, I prefer to protect the upper portion also in the same way. There is one thing I would mention with respect to the Fuller cell, and which, in the hands of amateurs, proves a frequent cause of failure. It is the connection on the carbon. After a short time of use, the fluid is apt to creep up and destroy the connection with the binding screws. When these are cast on in lead, it also aggravates matters. My plan is to soak the top of the carbon in paraffin wax; then drive the paraffin down the plate, say, ¼in., and then electrotype the top. To this you may solder any-shaped binder you like, and the fluid never is able to destroy the connection. The makers for the patentee use a lead cap protected with paraffin; but I greatly prefer a copper connection, as mentioned.—Sunlight.

[11138.]—Midland Railway.—I am much obliged to "Cambridge" for his reply to my query. Will he kindly say whether the distances to Manchester and Liverpool are rel Trent Station? Will he also give the shortest distance to Liverpool [illegible]

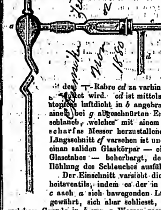
Ein einfaches Rückschlagsventil für Wasserstrahlluftpumpen.
Von Prof. R. Otto.[4])

Um bei Druckschwankungen in der Wasserleitung oder plötzlichem Abstellen des Wasserzuflusses ein Zurücksaugen des abfliessenden Wassers in den evacuirten Raum zu verhindern, schaltet man entweder zwischen Pumpe und Kolben eine Sicherheitsflasche ein, oder man bringt an den Pumpen besondere Ventile an, welche einen Rückschlag des Wassers überhaupt nicht gestatten.

Als äusserst zweckmässig empfiehlt Verfasser das von seinem Assistenten Dr. Pauly construirte. Diese einfache Vorrichtung besteht aus einer Glasröhre b (siehe beistehende Zeichnung), welche zwischen die Pumpe a und das zu evacuirende mit dem T-Rohre cd zu verbindende Gefäss eingesetzt wird. cd ist mittelst eines Kautschukstopfens luftdicht in b angebracht und endigt in einem bei g abgeschnürten Endchen Kautschukschlauch, welches mit einem durch ein recht scharfes Messer herzustellenden, penetrirenden Längsschnitt ef versehen ist und in seinem Innern einen soliden Glaskörper — ein Stückchen eines Glasstabes — beherbergt, der nicht völlig die Höhlung des Schlauches ausfüllt.



a

d

Chemiker Zeitung Nov 25 1880

Der Einschnitt versieht die Stelle des Sicherheitsventils, indem es der in der Richtung von c nach a sich bewegenden Luft den Durchtritt gewährt, sich aber schliesst, sobald aus irgend welchem Grunde in b von a Wasser gesogen wird.

Dies Ventil hat sich durchaus bewährt, ebenso die in der Zeichnung dargestellte, von Geissler ganz aus Glas construirte Pumpe.

The Electrician, July 2, 1881.

5033. Improvements in Electric Lamps. *J. H. Johnson.—3rd December, 1880.—(A communication from A. de Meritens.)—(Not proceeded with.)* 2d.

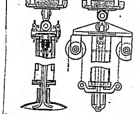
This invention has for its object the production of light by means of iron rendered incandescent by electricity. The ends of two conductors are connected with two iron wires, terminating in small balls, and supported by two insulated and adjustable supports placed upon a table. The iron balls soon become red-hot, and afterwards incandescent at a white heat, but do not melt.

The Electrician, July 16th 1881.

4755. Improvements in Electric Lamps and Apparatus Connected Therewith, *J. A. Berly and J. D. Hulett.—18th November, 1880.* 8d.

This invention relates to an apparatus for suspending electric lamps so as to enable the said lamps to be pulled down, detached, &c., to be regulated or attended to, and pushed back into their former position whilst alight. Fig. 1 is an elevation, and Fig. 2 a longitudinal section of the apparatus. In whatever position the sliding portion of the apparatus may be, the currents

4755



from the circuit wires attached to the terminals N will be conveyed to the strips of metal J and collected by the friction pieces G, from which, through bolts, F, to which they are electrically connected, the second currents will be conveyed to the lamps by means of the conducting wires attached to the heads of the bolts F. The whole apparatus being enclosed, is free from dust and not liable to be damaged, which ensures regularity of working.

THE SUN ELECTRIC LAMP.

La lampe soleil, as it is termed, is a new French electric lamp of considerable promise and some novelty. The light is formed by boring two converging holes into a small block or brick of marble, and inserting into these two carbon rods. The rods are separated at their points by a partition of the marble, and they nearly penetrate through the block. Their upper ends are connected to the dynamo-electric machine, and the current in traversing the wall of marble between their points makes it white hot. The carbons are slowly consumed, the gas escaping from the bore-holes, which are wider than the rods, and they are fed to the arc by their own gravity. The light is admitted by the bottom of the brick, which becomes calcined, and is of a mellow lustre like the sunshine. The cost is said to be only a sou per hour, the carbons consuming at the rate of a centimetre in that time. Already *la lampe soleil* has been introduced into several places in Paris, including the mayor's residence, and it will form a feature of the forthcoming exhibition. It is the invention of MM. Clerac and Bureau; but it reminds us of the electro-calcic lamp patented by Mr. Wentworth L. Scott in 1878, wherein a block of lime or other earth is interposed between the electrodes of the arc. Mr. Scott did not arrange his apparatus like the sun lamp; but his intention was, we understand, to heat a piece of lime white hot by the current, just as it is heated by the mingling gases in the Drummond limelight.—*Engineering.*

AN IMPROVED METHOD OF OPERATING THE SPRENGEL AIR-PUMP.*

By Professor Ogden N. Rood.

Professor Rood's paper gave an account of his experiments with the pump for the purpose of obtaining the highest possible vacua. He first experimented with an arrangement similar to the ordinary form of the Sprengel pump, and reduced the pressure to one three-millionth. The exhaustion went on very rapidly at first and then very slowly—slower than the increased rarefaction seemed to call for. This indicated a leakage, and it was found that this leakage amounted in one minute to one-eighty-seven-millionth of an atmosphere. The form of the pump was modified to correct the leakage, and a vacuum was obtained with a pressure of one-sixty-millionth. It was impossible to get beyond that point, and it occurred to Professor Rood that the potash he used might have given out moisture. He therefore substituted sodium, and the pressure rose only to one-four-millionth. Anhydrous phosphoric acid was substituted for the sodium, and the pressure fell to one-millionth. It finally struck the experimenter that the trouble was in the gauge, and when a correction was applied to the gauge, vacua were obtained with pressures of one ninety-four-millionth and one-hundred-and-ten-millionth. Higher vacua even can be obtained.

It had recently been stated in *Nature*, said Professor Rood, that this arrangement was exhibited four years ago at the Kensington Garden, and he would not, therefore, call it new. But the best result obtained in England was one-twenty-millionth, and the best result reached by an eminent French chemist was one-seventeen-millionth. He, therefore, thought there must be at least something new in his method of using the Sprengel air-pump.

* Read before the National Academy of Sciences, N. Y., 1880.

REPORT OF THE COMMISSIONER OF EDUCATION, FOR 1878.

[*Extracts.*]

TEXT-BOOKS AND COURSES OF STUDY.

The lack of uniformity in the conditions of public education in the different States is illustrated in the report on text-books and courses of study.

Returns from 31 States present the following information:

The State board is empowered to decide these matters in California, Connecticut, Delaware, Louisiana, Nevada, and Oregon. In Kansas, Nebraska, New York, and Rhode Island, the State superintendent or commissioner has authority to recommend the text-books to be used, but their adoption and the course of study are finally decided by the school committee or district boards. In Iowa and South Carolina these matters have been decided by a commission appointed for the purpose. In Maine, authority in these matters is delegated to the town supervisor or school committee; in Maryland, to the county commissioners; in Massachusetts, to the school committee; in New Jersey, to school trustees of districts acting with the county superintendents; and in Pennsylvania, to the directors and controllers of each school district, acting with the teachers. District or local boards either solely or acting in concert with superintendents and teachers decide these matters in Michigan, Mississippi, Missouri, Ohio, and Wisconsin.

In the following States—Minnesota, New Hampshire, Tennessee, Texas, Virginia, and West Virginia—the course of study is prescribed by law, but in the application discretion is given to superintendents, local boards, teachers, &c.

In Indiana, North Carolina, and Vermont no definite provision with reference to these matters has been made.

UNIVERSITIES AND COLLEGES.

The total number of universities and colleges reported is 358, with 3,885 instructors and 57,687 pupils. In the preparatory departments of these institutions were 682 instructors and 26,266 students; in the collegiate departments, 3,203 instructors and 30,368 students; unclassified, 1,353. They had 2,187,932 volumes in their libraries, and the value of their buildings, grounds, and apparatus was $36,871,213; their productive funds, $37,071,958; income from these funds, $2,548,324; receipts from tuition, $1,555,484; receipts from State appropriations, $622,577; aggregate amount of scholarship funds, $1,719,426.

Of the students in the preparatory departments, 18,481 are males and 6779 females; 6,576 are preparing for a classical course and 5,621 for a scientific course. In the collegiate departments, 15,803 (14,152 males and 1,651 females) are in classical course, and 3,893 (2,724 males and 1,169 females) are in scientific course.

The summary of college entrance examinations gives the following facts: Total number of candidates, 5,297; admitted without conditions, 2,553; conditioned in Latin, 822; in Greek, 577; in mathematics, 1,068; in history and geography, 585; rejected for deficiency in Latin, 84; in Greek, 70; in mathematics, 66; in history and geography, 22; in two or more subjects of examination, 424.

There are also statements of the numbers preparing for college, classical, and scientific courses, as follows: number preparing for classical course in academies, 6,206; in preparatory schools, 4,195; in universities and colleges, 6,576; preparing for scientific course: in academies, 2,167; in preparatory schools, 1,107; in universities and colleges, 5,621; in preparatory departments of scientific schools, 1,550; total, 27,422.

Students in institutions for superior instruction are distributed thus, viz.: in colleges, 30,368; in schools of science, 11,603; in schools for the superior instruction of women, 18,115; in all 60,086.

The Commissioner presents a brief outline of the movement in colleges to satisfy the demand that the study of science and sociology be advanced to an equality with the classics and mathematics. Without sacrificing anything of the former curriculum, temporary provision for the new studies has been made in most instances by a system of electives. The action is traced through the record of Harvard and Yale Colleges, and the views of Dr. McCosh, president of Princeton College, Dr. Peabody, of Harvard University, and Prof. B. L. Gildersleeve, of Johns Hopkins University, with reference to the most important conditions of the change, are cited.

Some have feared that in this readjustment of college courses the classics would be sacrificed, but the present tendency is toward greater thoroughness and a more extended range in classical studies; nor under the elective system is the number of students who take the modern in place of the classical course sufficiently large to create any apprehension as to the future influence of classical study.

The prevalent views on this subject are well represented in letters from Professor Haeckel of Jena and Professor Zarncke of Leipzig, which are given in full in the report.

SCHOOLS OF SCIENCE.

Of this class 76 schools, including the United States Naval and Military Academies, were reported to the Bureau. They numbered 809 instructors and 13,153 students. The comparative table for the years from 1870 to 1878, inclusive, shows this to be an increase in all particulars over the figures reported for any previous year. The increase above 1877 was in number of schools, 2; instructors, 28; students, 4,594. The number of students in preparatory departments was 1,436, viz.: 1,153 males and 283 females; the number in scientific departments was in regular course, 4,806; in partial course, 772; number of graduate students, 97. The number of volumes in general libraries was 119,164, an increase in the last school year of 3,543; the number in society libraries was 7,737. The value of grounds, buildings, and apparatus reported, was $7,587,421; productive funds, $5,020,446; income from the same, $319,503; receipts from tuition fees, $68,660; from State appropriations, $484,742.

With reference to schools of science the Commissioner observes:

"By the act of 1862 donating public lands to the several States and Territories which should provide colleges for the benefit of agriculture and the mechanic arts, the movement

ous wings and were probably aquatic in early life. The last statement is simply inferred from the fact that all the modern types most nearly allied to them are now aquatic.

"Some of the Devonian Insects are plainly precursors of existing forms, while others seem to have left no trace. The best examples of the former are Platephemera, an aberrant form of an existing family; and Homothetus which, while totally different in the combination of its characters from anything known among living or fossil insects, is the only Palæozoic insect possessing that peculiar arrangement of veins found at the base of the wings in Odonata typified by the arculus, a structure previously known only as early as the Jurassic. Examples of the latter are Gerephemera, which has a multiplicity of simple parallel veins next the costal margin of the wing, such as no other insect ancient or modern is known to possess; and Xenoneura, were the relationship of the internomedian branches to each other and to the rest of the wing is altogether abnormal.

"If, too, the concentric ridges, formerly interpreted by me as possibly representing a stridulating organ, should eventually be proved an actual part of the wing, we should have here a structure which has never since been repeated even in any modified form.

"They show a remarkable variety of structure, indicating an abundance of insect life at that epoch.

"The Devonian Insects also differ remarkably from all other known types, ancient or modern; and some of them appear to be even more complicated than their nearest living allies.

"We appear, therefore, to be no nearer the beginning of things in the Devonian epoch than in the Carboniferous, so far as either greater unity or simplicity of structure is concerned; and these earlier forms cannot be used to any better advantage than the Carboniferous types in support of any special theory of the origin of insects.

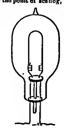
"Finally, while there are some forms which, to some degree, bear out expectations based on the general derivative hypothesis of structural development, there are quite as many which are altogether unexpected, and cannot be explained by that theory without involving suppositions for which no facts can at present be adduced."

The Electrician, July 16. 1881.

239,153. Electric Lamp, *Thomas A. Edison, Menlo Park, N.J.—Filed August* 27th, 1880.

Claim.—(1). The combination with the glass enclosing globe and incandescing conductor of an electric lamp, of a support hermetically sealed to the globe, and supporting the carbons at a distance above the point of sealing, substantially as

239,153



set forth. (2). The combination, with the conductors of an incandescent electric lamp, of a glass support, to which the conductors are sealed at two or more points, one near the clamps and one where the conductors enter the enclosing globe, so that the latter point is removed a little distance from the former, substantially as set forth.

The Tradesman Oct. 15, 1881.

The London Athenæum says that M. Jamin has made a considerable advance in the arrangement of his electrical candle. He incloses his carbon loop in a carefully closed vessel containing air. The electric action at first produces the combination of the oxygen and nitrogen of the atmosphere, and the usual colored vapors are seen; these are soon destroyed by the oxygen combining with the carbon, nitrogen and carbonic oxide alone remaining in the glass globe. The phosphorescent arc then becomes quite fixed, giving light of a greenish blue tint. Each candle, by this arrangement, lasts 100 hours.

94

A NEW AUTOMATIC ELECTRIC LAMP.

We illustrate on this page a new automatic electric lamp made on what is known as the Heinrich system; and which we find described in a recent number of a British scientific journal. One of the distinctive features of Mr. Heinrich's idea is the employment of curved carbon rods, which abut upon each other slightly at their points of intersection. The planes of the two circles are perpendicular to one another, as shown in Figure 14. The upper pair are both positive, being connected to the positive pole of the dynamo-electric generator, and the lower pair are negative, being in electrical connection with the other terminal of the machine. The feed of the carbons requires no mechanical apparatus such as clockwork or gearing, but is determined solely by the mechanical wasting away through the consumption of the carbon rods at their point of contact, the rods falling together by their own weight, as the carbon at their point of contact is dissipated by the action of the current.

While the feed of the carbons is determined by their consumption, the regulation of the length of the arc is effected by electrical means, the strength of the current flowing at any one time determining, by the simple contrivances shown in the sectional view, the degree of approach or separation of the carbon rings. On referring to Fig. 15 it will be seen that the upper or positive pair of carbon holders a^1 and a^2 are so pivoted at s^1 and s^2 that their swing is made equal and symmetrical on both sides. A similar method is adopted with the arms of the negative carbons. This motion is obtained from the crank lever l, which in turn is operated by a current from an electro magnet M. To prevent a sudden jerk in this lighting which might upset the adjustment of other lamps in the circuit, an ingenious checking apparatus, consisting of a small rack forming a part of the rod f, which gears into a small pinion p^1, is provided.

In order to prevent other lamps in the same circuit from being disturbed by a break in the current through the carbons, a coil of German silver wire, of about equal resistance to the arc, is provided, and in case of such break the current is at once automatically shifted to and passes over the wire and the other lamps are not affected by the interruption. This device also enables one of the lamps to be extinguished without disturbing the others. The carbon rings are made by compression between dies, and are then cut in halves varying from 10 to 14 inches. The diameters generally used burn from 20 to 30 hours.

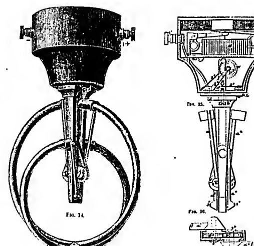


Fig. 14. Fig. 15. Fig. 16.

HEINRICH'S AUTOMATIC ELECTRIC LAMP.

95

LAMPE ÉLECTRIQUE DE JOEL

Ce nouveau système d'éclairage, qui semble avoir de l'avenir, a été installé dans les bureaux de la « Prudential Assurance Company » Holborn-Bars, par MM. Rowatt et Fife, Electric Light Company. La moitié de l'étage qui est immense est éclairée au moyen de neul lampes Joel de cent-cinquante bougies chacune et qui remplacent quarante-cinq becs de gaz; l'autre moitié de l'étage est encore éclairée au gaz. Le contraste qui existe entre ces deux éclairages est frappant sous tous les rapports. La lumière électrique permet de voir les diverses cartes d'assurances de la Compagnie, avec leurs couleurs naturelles, chose fort commode pour le personnel; l'atmosphère peut être maintenue beaucoup plus fraîche qu'avec l'aocien système d'éclairage au gaz.

La lampe Joel est un perfectionnement de la lampe Werdermann, qui a été installée à l'Opéra de Paris ; elle convient fort bieo à l'éclairage des bureaux.

Le brûleur est composé d'un crayon de charbon reposant sur un bouton de cuivre. — Le courant positif, en passant du charboo dans le cuivre, chauffe le craynn jusqu'à l'incandescence. Mais il y a en outre un petit arc en forme de perle au point de jonction du charbon et du cuivre lequel augmente sensiblement l'intensité de la lumière sans cependant diminuer sa stabilité. C'est donc un intermédiaire entre l'arc électrique proprement dit et la lumière purement incandesceote d'Edison, Swan, Maxim et autres.

Cette lampe n'est peut-être pas aussi petite ni aussi portative que les autres lampes; mais sa plus grande puissance est un sensible avantage dans bien des cas.

Les neuf lampes du « Prudential Assurance Office » sont alimentées par une machine B. de Gramme, de faible tension, mise en action par une locomobile de la force de vingt chevaux installée dans le local même. La force absorbée est estimée à trois chevaux et demi. D'après le rapport du professeur W. G. Adams, le système Joel peut fournir une lumière de sept-cent-quinze bougies par cheval-vapeur.

96 Ironmonger Jan. 24. 1880. (London)

EDISON'S ELECTRIC LAMP.

(FROM OUR SPECIAL CORRESPONDENT.)

NEW YORK: January 7.

HAVING promised in my last letter to give your readers some account of Mr. Edison's new electric light, and of the public test of its qualities made on New Year's Eve at the famous Menlo Park laboratory of this remarkable genius, I shall endeavour to keep my promise within the least space that will permit a description of the apparatus and its working. The Edison lamp, like most useful inventions intended for the general public, is very cheap, simple, and durable. It is not generally known that Edison has for the time abandoned the idea of using platinum, and that his light is obtained from incandescent carbon. But the carbon is not of the kind used in previous lamps, nor is it used in the same way as hitherto. The carbons of the Edison lamp are made from paper in the shape of a horseshoe. After being cut in the proper shape by a die, they are subjected to a heat sufficient to drive off all volatile matter contained in the fibre. This is done by packing them in tightly-sealed boxes and heating in a muffle. These carbon loops are clamped at either end between the jaws of platinum vices of almost microscopic size, which are supported by small platinum wires blown in the glass base of the lamp and forming the electrodes. The whole is then enclosed in a glass globe, about the size and almost the shape of a Duchess pear, from which the air is exhausted by a Sprengle pump until only one-millionth of its original volume remains. This is as near a perfect vacuum as it is necessary to get. The light is secured by passing the current from one electrode to the other through the loop of carbon, which offers a resistance equal to 100 ohms, and such a lamp as I have described will give a light ranging from one to ten four-foot gas-burners as desired. The carbon lamp is very tough, and is not liable to injury from accidental jars. It is also proof against injury from the sudden turning on and off of the current. In use the lamps are connected in multiple arc, and as Mr. Edison has arranged them it makes no difference in the volume or steadiness of the light from one lamp whether one is used or fifty—though of course it makes a difference in the power consumed in the generator. The regulation of the current is effected by the simple expedient of varying the intensity of the magnetic field in which the armature of the generator revolves. The entire apparatus consists of a few wires and the lamps. There are no regulators, no switches, no resistance coils, to compensate for the disuse of a part of the total number of lamps when all are not needed. In fact, the lamp is practically as simple as a candle, and may be moved as far as the slack of its connecting-wires may permit without interruption of the current. Attached to the electrodes are two strips of copper, which are bent upwards towards the glass, and touch two springs at opposite sides of the socket. One of these springs is connected with one of the electric conductors; the other merely touches the copper strip nearest to it, and does not form part of the conductor until the turning of a thumb-screw brings it into connection with the second conducting-wire. Turning this thumb-screw in or out causes the light or stops it. As an impartial reporter of events happening on this side of the Atlantic, I am compelled to say that, so far as my observation goes, Mr. Edison's light is as satisfactory in operation as it is simple in construction. The exhibition at the Menlo Park laboratory on New Year's Eve was, it seems to me, calculated to convince the most sceptical, unless the genuineness of the demonstration is doubted, and it is not questioned here. The laboratory was illuminated by twenty-five electric lamps; there were eight more in the office, and twenty others were distributed about the neighbourhood, lighting the streets and adjacent houses. Attempts were made by visitors, who are believed to have been connected with the gas interest, to tamper with the apparatus, but no accidents occurred, and every experiment made was entirely successful. Very few here doubt that Edison has solved the problem of domestic illumination by electricity. The durability of the lamps has been determined experimentally, by turning on and off the current very rapidly as many times as it would probably be turned on and off in thirty years of actual use in the household. In fact, everything has been done which sceptical scientists have suggested as calculated to satisfy them. The current is obtained from a magneto-electric engine, which may be run by steam, heat, or water power. Mr. Edison will use in connection with his light an electric motor, which, when illumination is not needed, can be employed for any of the ordinary purposes for which power may be needed in the household—raising water, running a sewing-machine, &c. He is confident that the cost of power by day and abundant illumination by night will be found less in practice than that of using gas at night. On this subject I shall probably be able to give you fuller information at some future time. At present I can only say of my own knowledge that his lamp is all that could be desired; that the light is steady, uniform, and agreeable, and that with one which might be carried without inconvenience in a coat-pocket, your readers would have but little trouble in reading the correspondence columns of THE IRONMONGER at a distance of from 80 to 100 feet. The gas companies are badly frightened—more so than at any time since the electric light began to be a matter of public interest. In the face of actual demonstration they derive but little consolation from the assurances of their trusted scientific advisers that the electric light is impracticable for domestic use. Behind Mr. Edison stands a very strong company of enterprising capitalists, who are only waiting the completion of necessary arrangements to push the introduction of the new system. Edison certainly deserves great credit for the originality of his investigations and experiments. He has but small opinion of the large class of conceited scientists who, with much theoretical, and but little practical, knowledge, are so ready to affirm what can and what can not be done. He has still less faith in the dogmatic utterances of book-makers. He says that the so-called information gained from books has almost always led him astray, and that his only real successes have been attained by determining for himself the properties of substances, and their relations to each other. This is unquestionably true, since in his experimentation he has made many important incidental discoveries which are important contributions to the world's knowledge in physical science. He is, without doubt, the greatest mechanical genius of this century.

[Since the above was written we learn that Mr. Edison has discovered that defective vacuums have developed in a considerable percentage of the lamps, but this difficulty Mr. Edison, according to his friends, will easily overcome. Meanwhile, the manufacture of additional lamps has been delayed.—ED. IRONMONGER.]

EDISON'S ELECTRIC CANDLES.

ANOTHER step in the development of the application of electricity to lighting purposes has to be recorded, Mr. Edison's second invention patented in this country having been published at the Great Seal Patent Office. It is entitled "Improvements in Lighting by Electricity." The letters patent bear date November 7, 1878, and the final specification was filed on the 7th inst., by Edward Griffith Brewer, agent, Chancery Lane, on behalf of Thomas Alva Edison, of Menlo Park, State of New Jersey, U.S. As set forth by the patentee in the specification, the special feature of the invention relates to the candle for the diffusion of the electric light. Mr. Edison's candle is in the form of a slightly tapering hollow cylinder, divided vertically except at the upper end. By this arrangement he claims that uniformity and complete incandescence are secured as the electric current passed up one side and down the other. At the base of the cylinder, which is enlarged for the purpose, the electric conductors are connected. A thermal circuit regulator, which has been described in an earlier patent recently published, is attached at the bottom of the candle, and is so arranged that if the current becomes excessive, the regulator becomes heated, and consequently expands so as to bring a movable spring into contact with the adjusting screw of the illuminating apparatus, and thereby diverts the current and lessens its action in the light. Mr. Edison specifies the materials of composition and method of manufacturing the light-giving substance, the essential condition of which is necessarily its power to resist fusion by the heat developed in the passage of the current. He says:—"Metals or oxides of metals are made use of which produce in a comparatively large candle sufficient resistance to render the whole incandescent. Finely divided metal or particles of metal having a high melting point are caused to adhere by earthy materials, such as magnesium or zircon oxides or magnetic oxide of iron, or other substances that are with difficulty fused. The oxides of metals may be obtained by chemical precipitation or otherwise, and the candle is moulded either in a dry or moist condition by pressure. The fine particles of metal may be platinum, iridium, ruthinum, or other metal." The patentee then details the mode of manufacture—"In cases where these oxides or earthy materials are mixed with the fine metallic particles such particles are thoroughly and uniformly mixed into a mass before it is moulded, and hence such particles are kept separate by the earthy material, and cannot fuse or run together, and the metallic oxides themselves are electric conductors to a greater or less extent, and hence may in some instances be used without the particles of metal. In all cases the substances are moulded and pressed into shape under powerful pressure, and if the particles do not adhere together sufficiently, sugar, tar, silica, or similar substances may be used in moulding the candle into shape, and these substances may be volatilised by the heat. The metallic particles are rendered highly incandescent, and the earthy substances and oxides are also rendered luminous by the passage of the electric current." Finally, the patentee declares that his invention "is not limited to any particular form in which the candle may be moulded or otherwise shaped; but it relates to the materials employed in such candles, whereby the mass is adapted to the passage of the electric current, and it is rendered highly luminous or incandescent by such current." In the statement of claims appended to the specification Mr. Edison sets forth as follows:—"What is claimed as the invention secured by these letters patent is that a candle or light-giving body for electric lights, in which particles of metal, or metallic oxides, are moulded into a mass, is adapted to the passage of the electric current, and made luminous by the same, substantially as set forth." Drawings, illustrating the form of construction and use of the apparatus, accompany the specification.

The Electric Arc.

Editors Electrical Review:

With the view of demonstrating that the vaporization of the positive electrode was essential to the production of the electric arc, the writer tried an experiment some time since which may interest others.

A disk of sheet copper, about 5¾ inches diameter, was placed in a lathe, and rotated at a speed of about three thousand revolutions per minute, the lathe being connected to the positive pole of a dynamo and the negative wire placed against the periphery of the disk, water being also supplied to the disk by means of a moist sponge held against it.

It was observed that at times there would be a failure to obtain an arc by removing the negative wire; but this may have been due to an interposed failure of water, for without the water an arc was apparently formed, although the conditions under which the experiment was performed rendered it impossible to be certain that it was not merely a rapid succession of contacts, producing sparks.

It is suggested to those having facilities for the experiment that two large disks, rolling against each other at a high speed, would be preferable, as the rubbing contact, which causes considerable heat at a high speed, would be thus avoided.

Owing to its higher specific heat, iron might be preferable to copper.

The Invention of the Incandescent Lamp.

To the Editor of The Electrical World:

SIR: In your last issue Mr. Richard N. Dyer, one of the Edison company's patent attorneys, puts forth a manifesto intended probably to assist your readers to accept the statement made by the Edison Company in their new advertisement to the effect that "the Incandescent Electric Lamp is the universally acknowledged invention of Thomas Alva Edison." These be brave words, but it is reported that the Edison stockholders have been recently assessed for the purpose of defending suits brought against their company for the unauthorized use of the incandescent lamp! The acknowledgment is scarcely *universal*.

Mr. Dyer travels over the well-worn track of the Edison supporters. The three elements are there again—the receiver entirely of glass, from which the air is exhausted, platinum wires sealed into the glass, and an incandescing carbon "filament" (there is some magic spell for an Edison man in the word "filament") within the globe, such filament being of "high" resistance. Mr. Dyer does not tell us what is "high" or "low;" the previous experimentalists, he says, failed because their carbons were of too low resistance. How "high" may a carbon be without infringing the "fundamental" patents of the Edison Company?

It would have been well if Mr. Dyer had stated whether he supported the claims of the Edison Company from the standpoint that Edison was the inventor of the incandescent lamp scientifically speaking, or within the meaning and for the purpose of the U. S. patent laws. He must surely mean the latter, but then unfortunately the Patent Office after a fight of five years has decided against him, and, not being able to revoke the "fundamental" patent already issued to Mr. Dyer's client, has issued a "fundamental" patent for the same invention to the representatives of Sawyer & Man. Of course Mr. Dyer may say that decision is all wrong (the defeated party generally does say that), but it is the only one that exists on the point at issue at the present time. If, as Mr. Dyer says, the Sawyer-Man lamp was not such "a practical and commercial success" as Edison's, possibly Messrs. Drexel, Morgan & Co. and the capitalists who put money into the one but not into the other project are to some extent to be credited with that. Perhaps they should be considered as joint inventors. A. T. Stewart made "a practical and commercial success," but he did not claim to be the "universally acknowledged" inventor of calico. There are plenty of valuable inventions that are not "a practical and commercial" success simply because they and capital have not been brought together.

A point to be remembered is that the decision of the Patent Office in the case referred to only related to the question of priority as between the parties. With reference to the three elements of the claims of the Edison Company, Mr. Dyer will probably not dispute the fact that they were all old and well known; but he will say, the combination of them all "substantially as and for the purposes described" involved invention, and was new. He has referred to experimentalists. If he will refer to *Philosophical Transactions* for 1876, Vol. 166, p. 351, he will see that an experimentalist used a receiver from which the air was exhausted and which was entirely of glass; this receiver had platinum wires passing through the glass to which they were directly sealed by fusion, and these wires conveyed current to an incandescing filament of platinum. If he will refer to *La Nature* for the 7th of December, 1878, he will find that M. Niaudet, in an article on the divisibility of the electric light, says that one of the principal inconveniences of metallic wires is that if the current is not regulated, melting of the wire occurs, and that the idea of employing carbon in place of metals appears to belong to King, and to date from 1845. Probably you do not care to try the validity of the Edison patents in your columns, but the two references given above seem remarkably pertinent, and they were not given by the Patent Office on Mr. Edison's applying for his "fundamental" patents. In fact, the office appears to have scarcely looked at the state of the art at all, for some reason or other. Mr. Dyer can, no doubt, give some explanation of the points briefly referred to in this imperfect communication, which I shall be glad to see supplemented by others of greater weight.

If the Edison Company or Mr. Dyer desire to discuss this question it will be interesting, if not profitable; but there is an impression abroad that the Edison Company will be wise to confine their claims to the many valuable improvements which do belong to them, and not lose what they have by trying to claim the whole earth.

A Miner's Electric Lamp.

At the recent conference of the Miners' Union, in England, Mr. Burt, M. P., the president, observed that two things were very desirable by the way of lessening the number of explosions. One was the provision of a good, useful light, and the other the abolition of blasting by gunpowder in fiery mines. We read in the London *Times* that the first of these conditions appears to be met by an apparatus which is self-contained and consists of a chloride of silver battery composed of three cells, each 6 in. high by 3 in. wide and 1 in. deep. The current produced supplies a small glow lamp, of German manufacture, which is placed in front of the metallic case containing the battery after the fashion of the bull's-eye of a police lantern. The lamp is well protected, and is provided with a reflector, so that a good light is thrown forwards. The light given by this lamp is stated to be of 3 candle-power, and to be capable of burning for nine hours, but this, as far as candle-power goes, is in excess of the requirement of the miner, so that smaller sizes are made. The cells are hermetically sealed, so that the lamp can be used at any angle without fear of loss of the liquid or extinction of the light as with the ordinary miners' oil lamp, than which the new one is said to cost much less for maintenance. Upon this point, remarks our contemporary, it is to be observed that when the power of the cells is exhausted there is no waste of the elements. The chloride of silver will have become converted into pure silver, and can be revivified by washing in a solution of nitric and hydrochloric acid. The lamp and the battery are both locked against the miner, who cannot interfere with either. The lamp can be hooked up in the ordinary way, or attached to the miner's belt. It has, says the paper, had the approval of one of the leading electricians, and of several mining authorities, subject to being tested.

London Eng. Globe. 8-19-86.

A NEW ELECTRIC LAMP.

An electric lamp for domestic use was yesterday afternoon exhibited by the Regent Primary Battery Company, at 17, Craven-street, Strand. This lamp is of simple construction, and seems to be a step in the right direction inasmuch as it is composed of a simple incandescent lamp, to which the current is supplied by a primary battery to which it is attached. The battery, comprising 28 cells of 2·6 volts each, is contained in a mahogany box rather less than a foot square, on which the lamp is fixed. The inventor states that these lamps will burn for eight hours, giving a light of 16 candles, and exhibiting a nominal resistance of 7·1 ohms. The battery can, we are informed, be renewed daily by any servant, and, when supplied with the necessary fluid, requires no further attention. The cost of this light is about double that of gas, and the lamps will be sold for a small sum.

Boston. Journal of Commerce. 3-13-86.

Something About Making Electric Lamps.

The incandescent electric light remarks a contemporary, has become a familiar object to everyone. The little glass bulbs with their brilliant horseshoe of glowing filament attract no more attention than the flickering gas jet. But the facts about the gas jet are easily and generally understood, while the electric lamp is still a puzzle to many people. Both produce light by incandescence. The molecules of gas are rendered incandescent by the heat generated by the combustion of other molecules. The blue portion of every gas flame is where combustion is taking place, and from that comes the heat which keep the rest in a state of incandescence. With the electric lamp it is the heat produced by the friction of an electric current compelled to go through a fine carbon filament, which raises that filament to a condition of incandescence and produces light.

The three substances which enter into the composition of an electric lamp are glass, platinum wire and bamboo or paper. Glass blobs are readily prepared by the usual methods of glass-blowing, but the preparation of the bamboo is a delicate piece of work. In the best lamps the little horseshoe is made of bamboo, and this material has proved its superiority to its rival, paper, in several ways. The bamboo comes from Japan in bundles of slips a foot in length. Japanese bamboo is of finer quality than the Chinese. It is first split up into little square strips. Girls round this off by running them through dies until they look like little broom straws. These are put in crucibles with graphite and submitted to a white heat for several hours. This carbonizes them thoroughly. The filaments are not all of exactly the same size when taken out of the crucibles, and if used in that state would present varying resistances to the current and the lamps would not be even and economical in their working. To make them uniform, they are put one by one into a glass jar from which the air can be exhausted and a hydrogen gas—the lightest of the products of petroleum—can be admitted. A current of electricity is run though the horseshoe filament and it absorbs carbon from the gas until the operator sees that its resistance has been reduced to the regulation amount. The standard used in the factory from which this description was obtained is 250 ohms. The moment when the resistance has reached the desired point is told by means of an apparatus familiar to electricians—the Wheatstone bridge.

Now, the lamp is in three parts: The bulb, the carbon filament, and the stopper, containing the two platinum wires which are to connect the horseshoe of carbon with the system of wires that carries the current all over a building to the hundreds of lamps. It only remains to put the stopper in its place at the larger end of the pear-shaped glass bulb, seal it air-tight in the flame of a blow pipe, extract the air from the bulb by a mercury pump and then seal the other end. The bulb is made of the thinnest glass, and before the air is exhausted from it will break easily. After the vacuum is created, however, it can be handled carelessly without injury; and when it does break there is a report like that of a dozen popguns.

The lamps are expected to burn 600 hours. Sometimes, like other articles of human manufacture, they fall short of expectations. The competitive trial recently made at the Franklin Institute of the lamps of various companies furnished several woful examples of this truth. A well-made lamp will last that length of time, however. If by bad workmanship air is allowed to leak in, the carbons burn out quickly. If it is run at too high a tension; that is, if too much current is sent through it, the friction wears out the little horseshoe in a shorter time and it breaks. It is the necessity for a practically absolute vacuum that requires the employment of the platinum connecting wires. Platinum is the only metal which expands and contracts with heat at the same rate as glass. This keeps the joint, where the wires pass through the glass, always tight, so that no air can enter. There is a fortune in store for the inventor who can get up some kind of cement that will prevent the passage of air, and at the same time admit the use of cheap copper instead of costly platinum wires. The problem may be capable of solution, for this whole matter of electric lighting is still in its infancy, though not a most vigorous stage of infancy.

Menlo Park Scrapbook, Cat. 1050

No. 35A. "Radiometer and Vacuum Pump"

This scrapbook covers the years 1874-1880 and contains clippings about radiometers and vacuum pumps. Between pages 110 and 111 is a note that a leaf was removed and placed on exhibit in the Patent Office interference proceedings between Edison and Ludwig Boehm. The spine is labeled "Vacuum Pump--Tube--Radiometer--Elect. Lamp." There are 126 numbered pages.

(10.) Repeated (5) and again proved the presence of phosphoric acid.

Remarks.—The presence of alumina or aluminum phosphate is seen from (3 b) and (8 a); of silica from (3 b) and (9); of lime from the white *balls*, which might, however, have been MgO. The presence of copper was so evident that it was unnecessary to use phosphoric acid as a detection.

The minuteness of these details (necessary where a process is described for the first time) makes the analysis appear much longer than it is, but the essential character of the mineral appears in operation (3), what follows that is chiefly confirmative.

September 19, 1876.

NOTE ON THE RADIOMETER.*

By WILLIAM CROOKES, F.R.S., &c.

During the last three months several papers have been read before the French Academy respecting the radiometer. On reading these papers I find that the various experiments performed are in general repetitions of some which I have devised during the four years I have been working at the subject. The descriptions of my experiments and the results I have obtained have been communicated by me from time to time to the Royal Society. Unfortunately, however, these papers do not appear in the *Philosophical Transactions* until twelve or eighteen months after they have been read, and according to custom I could not communicate them to other learned Societies. If these *savants* had seen my papers they would have found that I had not only tried the experiments, but that I had also discussed the evidence both for and against the several theories they have advanced to account for the action of the radiometer. The experiments with radiometers are almost all described in the third and fourth parts of my paper: these were read before the Society on February 10th, 1876, while in parts one and two I have considered the various supposed causes of the phenomena.

In the *Comptes Rendus* for July 3rd, 1876, M. Govi describes an experiment showing the action of dark heat on the instrument. This experiment is described in the paper read before the Royal Society on February 10th, and was also shown at a *Soirée* of the Royal Society on April 5th. The radiometers described by MM. Alvergniat and Gaiffe, in the *Comptes Rendus* of July 24, differ in nothing from those that I had previously caused to be constructed, and which are also described in the paper referred to above, while M. Ducretet's experiment of pouring ether upon the case of the radiometer was demonstrated to my audience on the occasion of my lecture at the Royal Institution, on February 11th, 1876. At the Royal Society *Soirée*, April 5th, I exhibited the turbine-radiometer, and this is also described in the paper read on February 10th. In the *Comptes Rendus* for June 19th a similar instrument is explained by M. de Fonvielle. With regard to the cause of the rotation, M. de Fonvielle adheres to the theory of emission; while M. Fizeau, in the *Comptes Rendus* of May 29th, attributes the action to, first, a slight excess of temperature acquired by the discs as compared with the ambient medium under the influence of light; secondly, to the unequal powers of emission and absorption of two opposite surfaces (black and polished) of each disc; thirdly, to the presence, in the apparatus, of a small quantity of elastic fluid. In the No. for June 19th M. Govi refers to Fresnel's experiments, which he will find described in my paper read in December, 1873; and he also says that, if the thermic currents of rarefied gases contained in the receiver do not suffice for explanation of the facts observed, there is another explanation, namely,

* Translated from a Letter to Count du Moncel, published in the *Comptes Rendus*, September 11, 1876.

Examination of the Possible Mechanical Action of Light: Study of the Radiometer of Mr. Crookes.—M. A. Ledieu (continuation).—The author having explained his theory to M. Fizeau, this eminent academician proposed an experiment by polarising a pencil of rays. In this manner, in fact, in accordance with his theory, we ought to obtain a minimum impulsion, or none at all when the plane of polarisation is made to pass along the axis of the radiometer. On the contrary, the maximum impulsion should be obtained at 90° from the first position. This experiment was made with an excellent instrument by M. Alvergniat, but it gave no conclusive result. M. Fizeau then caused an ordinary pencil of rays to fall exclusively upon the blackened discs, and thus obtained a movement more accelerated than when the pencil fell at once upon both kinds of surfaces. He then operated in an analogous manner upon the bright surfaces, taking care to incline the pencil of rays so that no reflection might be thrown from the polished surfaces upon the black ones. The instrument continued to revolve, but with a reduced speed. This latter experiment would lead us to condemn all radiant influence, since this would attract in one case and repel in the other. The author's theory would therefore seem confounded by such a result, as well as every other explanation based upon the doctrine of emission. But on examining more closely, we are led to remark that in all the experiments related there is reflection of light upon the glass of the globe, and that, besides, when these rays are polarised, the plane of polarisation, after reflection, is no longer presented in the same direction as regards the faces of the discs. We must then conclude that further experiments are absolutely required to elucidate the question. The author, then, quoting the opinion of M. Fizeau, given in the present number of the CHEMICAL NEWS, continues—"This opinion, emanating from so distinguished a *savant*, must assuredly be taken into high consideration. Nevertheless, considering the regularity, the definite character, and the certainty of the revolution of the instrument, always in one and the same direction, the explanation of M. Fizeau does not satisfy us entirely, and the debate does not seemed to be closed. He then suggests the following experiments:—Illuminate an ordinary radiometer, *i.e.*, with discs alternately polished and blackened in the direction of its axis. The instrument ought to revolve in the same direction as when the pencil of rays illuminates the axis vertically, and the rotation even ought to be accelerated. Second. Construct an apparatus all the discs of which shall be left bright so as to reduce to a minimum the influence of the reflections upon the glass; then to throw a pencil of rays upon the disc situate on one and the same side as relates to the axis of the instrument. If the rotation is really due to the mechanical action of light the instrument will turn as if the discs were repelled by the luminous rays. M. Ledieu does not hold that th[e] movements of the earth, as a whole, can be effected by th[e] solar radiations. He considers, however, that we hav[e] here a very natural explanation of the form of the tails o[f] comets.

Considerable attention was deservedly attracted by the experiments made during the evening by Mr. A. Apps, several of these experiments being among the most striking and beautiful within the vast range of electrical science. Nothing could surpass in richness of colour and softness of tint, his admirable combination of the fluorescent liquid and cascade experiment. An aurora tube 10 ft. long was lit up by an 15 in. induction coil, which, when connected with a large Leyden jar, gave the discharge a peculiarly snapping resonance. The diamagnetic property of copper was also shown, and many were very much amused with the time-honoured "poker" experiment.

Dec 75

Explanation of the Impressionability of the [B]lackened Discs of the Radiometer by the Aid of [th]e Emission Theory, according to J. B. Biot.—[M]. W. de Fonvielle.—J. B. Biot, in the third volume of [hi]s "Traité de Physique," explains how the luminous [m]olecules cannot communicate their *vis viva* to reflecting [s]urfaces. In fact, these latter exert a truly repulsive action [u]pon those molecules which, not touching them, cannot [p]roduce upon them any percussion similar to that im[p]ressed by electric forces. The considerations developed [b]y this illustrious physicist not being applicable to [b]lackened discs, we understand that the rotation of the radiometer should be produced in such a direction that they may fly from the ray. Is it not curious to find that the emission theory has permitted us to some extent, as far back as 1816, to foresee the experiment of Mr. Crookes? The explanation of the phenomenon, if we admit M. Biot's starting-point, does not require any new reasoning. The effort lost in the change of direction of the luminous molecules seems at first sight not to produce any effect, a result which does not appear reconcilable with the law of the conservation of the quantity of movement. Nevertheless, we may reply to this objection that according to the theory of emission this quantity of motion is represented by an internal ray performed upon the ray of light; for the direction of the axis of the luminous molecules has been changed since the reflection, for in place of being situated in the direction of the ray these axes have become perpendicular to that direction after the reflection. In this hypothesis the energy destroyed is represented by that which has been employed for the polarisation of the incident ray. The author has studied, along with M. Ruhmkorff, an apparatus known in Germany under the name of *light mill*—an appellation which seems to him scarcely justifiable, for the rotation of a wheel placed in the centre of a Geissler's tube seems exclusively produced by a dynamic effect peculiar to electricity, and in which light does not intervene in any manner. In fact, the vacuum is so imperfect that a radiometer placed in Geissler's tube cannot turn without the action of a ray of light. Further, the state of the surfaces has no influence upon the direction of rotation in Geissler's "mill," which is entirely bright, whilst the direction of this rotation is changed at will by altering the direction of the current. The preponderance of the negative flame, much more direct than the positive, cannot exert, as the author at first believed, any influence on this inversion, for a very sensitive radiometer, capable of being set in motion by the light from a smouldering match just blown out, was not moved by the light of an induction spark striking sufficiently near to the glass case to perforate it.

New Radiometric Experiments.—M. Collado.—The author has exposed a sensitive radiometer to the light of the full moon, and concentrated the light upon the blackened surfaces of the discs by means of lenses or of concave mirrors, but without perceiving any movement. In like manner, if a radiometer is submitted to the radiation of a single Bunsen burner the speed of the revolution is not altered if the pale blue flame is rendered luminous.

3

[ren]dered insensible, though it turned very quickly if a vacuum was made without heating in the ordinary manner. But if the discs, instead of being made of two metals, were made half of metal and half of mica the instrument could not be rendered insensible. The glass case was pierced by an electric discharge, when the radiometer began to turn with great speed, and continued for an hour. The aperture was so small that its diameter could be approximately estimated only by the aid of a powerful microscope. It was found practicable to re-form a vacuum in this instrument up to 100 m.m., even though perforated; rotation then took place in the ordinary manner. Nos. 6, 7, and 8, are radiometers with discs of mica and varnished copper, green, blue, red, and yellow; the colours, in these conditions, have no effect on the radiation.

Cause of the Motion of the Radiometer.—M. O. Saint.—According to all the experiments made, the cause of movement in the various apparatus resembling the radiometer of Crookes is a difference in the temperature of the surfaces of the discs. The theory of Tait appears the best. A disc, compound or simple, whose surfaces have actually two different temperatures, and which is plunged into a highly rarefied atmosphere, begins to move, the hottest surface recoiling. Whilst the difference of temperature exists the movement continues. There is no occasion to bring forward the possible action of gases condensed on the surfaces. Wherever two thermometers, isolated in a vacuum, and constructed of two different substances, A and B, would indicate different temperatures, a radiometer disc composed of adjacent laminæ, the one of the substance A and the other of B, will begin to move, and the movement will show the direction and the degree of the difference of temperature. In the circle of lights the discrepancy between the indications of two thermometers, the one with its bulb blackened maintained itself for an indefinite time; it is the same with the movement of the radiometer. Not content with repeating the experiment of Mr. Crookes and M. Fizeau, by placing the radiometer in the centre of a sphere of opal glass so as to equalise the light and avoid currents of air, the author has made an experiment which he considers absolutely demonstrative. He has fixed upon the mill of a radiometer the needle of a compass: the discs were composed of two laminæ of burnt mica, one of them blackened. Under the influence of an adjacent flame the needle deviated to a certain angle, and variations in the lustre or in the distance of the flame were shown very distinctly by a corresponding change in the deviation. The source of light having remained constant for four days the needle kept its position invariable for the whole of the time. The action of condensed gases cannot be invoked here.

4

Photometric Researches on Coloured Flames.—M. Gouy.—Not suitable for abstraction.

Note on the Radiometer.—M. A. Gaiffe.—The author has made a modification, which he considers proves that the actinic and thermic rays act upon this instrument. It is a radiometer of the ordinary form, the discs being coloured a dead blue on one surface and a dead red on the other. It may be made to revolve in either direction by using alternately suitable sources of heat and light. If, e.g., we expose this instrument to the sunlight, the blue surfaces acquire a predominant action, and after some moments hesitation the mill begins to turn from the left to the right. If it is exposed to the flame of a common gas-jet, or of a Bunsen burner, or to the radiations of a plate of hot iron the rotation takes place in an inverse direction.

Radiometers composed of Laminæ of Different Materials.—MM. Alvergniat Freres.—The following observations have been made with radiometers with discs of different materials. No. 1 is a radiometer with discs of silver and transparent mica. In the light the radiometer turns with the mica in front and the silver repelled; in obscure heat, with the radiometer plunged in water at 30° or 40°, the rotation is in the opposite direction. In ice it turns as if exposed to light. No. 2 is composed of aluminium and blackened mica. In the light this radiometer turns with the metal first, and the blackened surface repelled. Obscure heat and light, however intense, do not modify the direction of the rotation. If plunged in ice it turns in the opposite direction. No 3 is formed of aluminium and mica not blackened. In light this radiometer turns with the mica first. In ice the rotation is in the same direction as in light. Dark heat makes it turn in the opposite direction, with the metal first. With this radiometer M. Jamin made the following experiment:—He directed a small light upon one point of the radiometer while in motion, so as to heat only a single point of the globe. This threw the discs into such a state of equilibrium, that instead of rotation there ensued oscillations like those of a pendulum. The two surfaces of the discs, the metal and the mica, are both repelled: if the distance of the flame is varied one of the two laminæ is repelled more or less. No. 5 is a radiometer with discs of silver and aluminium. This radiometer has been heated to 440°, distilling sulphur, and continuing to make a vacuum with the aid of the mercurial pump. The instrument was ren-

Foreign Sources.

Radiometer of Mr. Crookes.—M. W. de Fonvielle.—The experiments executed by M. Datiu de Roissy and myself in the photometric laboratory of the gas works at Vilette appear to us to confirm the opinions put forward by Mr. Crookes. The procedure which enabled us to change at will the direct movement to the right into an inverse movement to the left seems to agree with the arguments of this eminent chemist before the Royal Society of London. We obtained the normal rotation under the action of radiant heat, but after having left the radiometer exposed for five minutes to a temperature of 45° C. we plunged it rapidly into a bath of cold water at 15° C. The rotation to the right ceased, the instrument stopped for a moment, and then began to revolve to the left with a rapidly increasing speed, which reached a revolution and a half per second. This inverse movement ceased almost as quickly as it had begun. At the end of half a minute the movement to the right re-commenced under the action of the solar rays which fell upon the absorbent surfaces of the radiometer in the midst of the liquid mass, and without the possibility of heating by conduction.

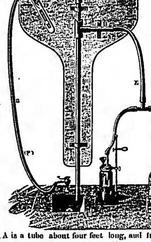
M. Fizeau, with reference to this communication, remarked that the conclusions of the author in favour of the existence of an impulsive force in the rays of light, seemed to him to require the most formal reservations. The ingenious instrument of Mr. Crookes seemed to be in reality a thermic-apparatus, in which the rotation, with all its circumstances, may be simply ascribed:—(1) To a slight excess of temperature acquired by the discs as compared with the ambient medium under the influence of light. (2) To the inequality of the emissive and absorbent powers of the two opposite surfaces of each disc, the one blackened and the other polished. (3) To the inevitable presence in the apparatus of a small quantity of elastic fluid (gas or watery vapour), the layers of which close to the blackened surface may acquire a slight excess of elastic force sufficient to propel the discs whose mobility is extreme. Certain inverse movements temporarily produced by cold will be the analogous results of the same causes. Moreover, M. Fizeau, at the request of several members of the Academy, made in their presence, at the end of the sitting, certain experiments with the instrument. He showed that if a stream of solar rays, limited by a screen, were thrown upon the disc so as to strike merely the polished surfaces of the discs the rotatory movement was still produced, but in such a direction that each disc moved to meet the solar rays instead of retiring from them, as ought to take place if the motion were the result of an impulsive power of light. Previous experiments have shown, further, that this result does not depend on accidental reflections in the interior of the apparatus.

[M]ODIFICATION OF THE JAGN VACUUM OR FILTER PUMP.

BY PROF. A. E. FOOTE.

[The] introduction of the Sprengel pump—so widely known since [Bunsen] applied it to rapid filtration—has been greatly limited by the [fact th]at most laboratories do not command the needful head of water. [The] pulsating pump, described in Liebig's *Annalen*, November, 1872, [is cap]able of producing a very good vacuum with a water fall of three [or four] feet. In adopting this pump for laboratory use, I found, in common with very many other persons, that the form given by the [inve]ntor has grave defects. Of these, the most troublesome lies in the caoutchouc valve, which, after a time, becomes stiff and acts imperfectly or not at all. The valve devised by Thorpe, described in the *Phil. Mag.*, October, 1872, has in my hands proved difficult of construction, works badly unless perfect, and quickly wears out.

My device is exceedingly simple and easily constructed. It can be made of common materials by any plumber or gas fitter. It has been [in] use in this laboratory for some months, and we easily produce by its vacuum of twenty-five inches of mercury. The following is a description of the apparatus as modified by myself:



A A is a tube about four feet long, and from three-eighths to one inch in diameter. To the side of this an arm B is affixed, by means of a "T" coupling. B is from four to eighth inches in length, and may have a manometer tube attached. C is the caoutchouc vibrating tube which conducts the supply of water to A. The upper part of A, over which C is thrust, is cut off at an angle of 40°. The vibrations are regulated by a moveable arm D. To B is attached a rubber tube E, which leads to the vacuum bell jar or bottle. Within B, and near its connection with A, is fixed by cement the valve represented in Fig. 2.

The valve is constructed as follows: A cylindrical metal plug about one inch long, and of such diameter as to slip easily within the tube B, is cut away at one end (as shown in fig. 2, where it is represented in section, with a portion of tube B), leaving a tongue of metal a. This tongue of metal is driven down upon a flap of sheet caoutchouc, about one millimeter in thickness, *b*, which is thus held upon the bevel of the plug, and covers the two channels c c, one of [which] is seen in section. These channels communicate with the pass[age] made by filing away tangentially the metal of the plug as sho[wn in] the cut. The caoutchouc flap is represented as lifted away fro[m the] face of the plug in order to show the orifices which it closes wh[en the] water current in the tube B is checked. These holes, in order [to be] perfectly closed by the flap, must be at least one-sixteenth of a[n inch] in diameter. The sheet caoutchouc should be as thin as possib[le]; the thinner it is the smaller the holes may be, and the better it w[orks]. It is absolutely necessary that the plug should be tightly com[pressed] into the tube, so that not a trace of air can leak through. A [stopcock] placed upon E, and used to retain the vacuum, may also be ma[de to] regulate the rapidity of exhaustion, but this may be done more [con]veniently by means of a stopcock F inserted in C, which regulat[es the] flow of water, or by means of a "globe valve" placed in the s[upply] pipe. The angle at which A is cut off at the top is also importan[t; if] not just right, the vibrations of the caoutchouc tube are not pe[rfect]. By the use of the ordinary gas fittings (stop cocks, pipes, etc.), we [have] connected one pump to several quite widely-removed bell jo[rs or] vacuum bottles.

I have been led thus fully to detail this piece of apparatus fr[om the] belief that, as soon as known, its simplicity, compactness, effi[ciency in] working and cheapness of construction will cause its general i[ntro]duction into laboratories even where a fall of thirty feet can b[e ob]tained without difficulty. Its value, not only for rapid and di[fficult] filtrations, but also for evaporations where the application of he[at is] objectionable, cannot be over-estimated.

I will here make note of a simple arrangement devised by one o[f my] students, Mr. F. D. Whitney, which quickens filtration sufficientl[y for] many purposes.

To the top of the shelving behind the sink fasten a tube vertic[ally]. Join one end of this to the water supply pipe, the other to the bo[wl of] a thistle tube, by means of a glass tube inserted through a r[ubber] cork; through another hole in the rubber cork is carried a tube w[hich] connects with a vacuum bottle. The vacuum produced is of co[urse] proportional to the column of water supported in the thistle tube [and] its connections.

For the platinum cone used in filtering, I take an old worn pie[ce of] platinum foil, one that has been used in blow pipe work, make it [per]fectly smooth, and cut it to the center on one side, bend it till it ne[arly] fits the bottom of the funnel, and then press it in place by means [of a] turned wooden cone. The more small holes in the foil the better.

I will add that these valves, as shown in Fig. 2, as well as [the] entire apparatus, Fig. 1, are made in the college workshops here, [and] will be furnished at cost on application to Professor Anthony.—*A[mer]ican Journal of Science and Arts.*

ON
ATTRACTION AND REPULSION RESULTING FROM RADIATION.*

By WILLIAM CROOKES, F.R.S., &c.

(Continued from page 24.)

44. The pump was now kept at full work for an hour. The gauge did not rise perceptibly; but the metallic hammering increased in sharpness, and I could see that a bubble or two of air had been carried down. On igniting the spiral, I found that the critical point had been passed. The sign had changed, and the action was faint but unmistakable *repulsion*. The pump was still kept going, and an observation was taken from time to time during several hours. The repulsion continued to increase. The tubes of the pump were now washed out with oil of vitriol,† and the working was continued for an hour.

FIG. 4C.

45. The action of the incandescent spiral was now found to be energetically repellent, whether it was placed above or below the brass ball (figs. 4 C, 4 D). The finger exerted a repellent action, as did also a warm glass rod, a spirit-flame, and a piece of hot copper.

46. I now heated the sulphuric acid, in the U-tube desiccator attached to the pump, until it boiled. A little aqueous vapour was driven off; the sharpness of the hammering of the mercury changed to a duller sound; and on trying an experiment once more with the ignited spiral, the action was seen to have returned to one of attraction.

On leaving the pump to itself for an hour or two, the sulphuric acid, as it cooled, again took up the aqueous vapour; and as the absorption proceeded I could trace the action of the hot spiral from attraction, through the point of neutrality, up to decided repulsion.

47. The critical point, in the case of brass balls, is much higher than with pith balls. In the case of pith, applying heat outside, I obtained neutrality when the gauge was about 7 millims. below the barometer, and decided repulsion when there was still a difference of a millims. With the apparatus just described, however, using brass balls and an internal source of heat, the critical point is very near the Sprengel vacuum. By close observation I can just distinguish that the gauge is a fraction of a millimetre below the barometer when the hot spiral ceases to exert an attractive action on the brass ball; but my unassisted eye is not able to detect a difference on the gauge between a Sprengel vacuum in which the ignited spiral is neutral to, and one in which it strongly repels, the brass ball.

48. I have experimental grounds for believing that the position of the critical point varies with the density of the mass on which radiation falls, with the relation of its mass to its surface, and with the temperature of the apparatus (62, 63, 64, 65, 67, 75). The temperature of the body used to attract or repel the brass or pith ball also affects the critical point, but it cannot, I think, modify it much; for with the apparatus last described no difference in kind of movement, but only in degree, was noticed, whether the spiral were ignited to full redness, or whether it were merely warmed by a momentary contact of the wires. Further experiments are in progress which may throw light on this point.

49. The very high amount of rarefaction needed before this neutral point is reached, and the change of direction of movement on applying a hot body to one arm of the balance, caused by a difference of exhaustion of a few millimetres on one side or the other of the point of neutrality, are, I think, a sufficient explanation of the anomalous results which were met with in my earlier experiments (2, 19, 20, 21, 22).

50. Although these results were sufficient to show that air-currents could not be the cause of the movements of the balance, I was anxious to decide this point once for all, by a form of experiment which, whilst it would settle the question indisputably, would be likely at the same time to afford information of much interest. Having found that the balance last experimented with had its neutral point close

FIG. 4D.

to an ordinary Sprengel vacuum, that the repulsive action only came on by still further pushing the exhaustion, and that, as I further exhausted, the repulsion got stronger, it was of interest to see what would take place in a vacuum so nearly perfect that it would not carry a current from a Ruhmkorff's coil.

In small tubes, and taking certain special precautions, I could prepare a vacuum with my Sprengel pump which would hardly allow an induction-current to traverse it, or would only show a faint, cloud-like discharge; but it was impossible to effect this in the large tubes required for these experiments, and, in fact, all the Sprengel vacuum balance-tubes which I had hitherto prepared became brightly luminous when the current from an induction-coil was passed through them. I accordingly fitted up the apparatus shown in figure 5, in which a chemical vacuum could be prepared by a method first devised by Dr. Andrews. (*Philosophical Magazine*, February, 1852).

51. *a b* is the tube containing a straw beam with pith ball terminals; at *b* two platinum wires are passed through, to connect with an induction-coil; at *a* the tube is contracted to allow the apparatus to be sealed off; *c* is a portion of the tube containing a copper boat filled with freshly cast sticks of caustic potash; *d* is a tube bent as shown, and nearly full of strong sulphuric acid, which has been previously boiled for some minutes and then allowed to cool in a vacuum; *e* is a mercury joint, connecting the apparatus to the Sprengel pump. At the upper part of the tube *d* is a stopper fitting into a funnel joint and capable of being replaced (as shown in figure) by a tube through which I could pass carbonic acid when desirable. The carbonic acid was prepared by the action of hydrochloric acid on marble; when not being passed into the exhausted tube, the gas was kept bubbling through mercury, where a tube full could be collected from time to time (as shown in the figure) to test with potash. It was found necessary to keep the evolution going on all the

* From the *Philosophical Transactions of the Royal Society of London* vol. clxiv., part 2.

† This can be effected without interfering with the exhaustion. See *Philosophical Transactions*, 1873, vol. clxiii. p. 296.)

absorbed until, in the course of from a few days to a few weeks, the vacuum will again cease to conduct.

54. It is very difficult to get the vacuum in large tubes so nearly absolute as not to allow a white, cloud-like discharge to pass. I have tried experiments with balances sealed up in vacua of both kinds prepared in this manner, and I always find the repulsion on the approach of a hot body is very decided, although I do not think it is more energetic than with the same kind of balance enclosed in the best Sprengel vacuum I could prepare. These experiments have therefore set at rest the doubts which might have arisen had I only worked with the Sprengel vacua, that air-currents were the cause of the phenomena. They have decided the important point, that in a chemical vacuum which will not carry an induction-current the repulsion by radiation is decided and energetic.

55. Besides the straw and pith balance mentioned above (51, 52), I have prepared and sealed up in chemical vacua balances made of a glass beam and platinum terminals, and also of glass entirely, the ends being flat glass plates. They act in all respects as the straw and pith balance, only being somewhat less sensitive.

56. The delicacy of one of the straw and pith balances in a good vacuum is very great, as may be comprehended by the following experiment:—The balance-tube was supported on a stand, and immediately beneath one of the pith balls was placed the face of a bismuth-antimony thermopile. On connecting the terminal wires of the pile with a single cell-battery, so that the current flowed in one direction, heat was produced, and the pith ball was repelled. On reversing the current, cold was produced and the pith ball was attracted.

57. The rays of the sun allowed to shine on the terminal pith ball of one of these delicate balances *in vacuo* repel it strongly. If concentrated by a lens the focal point beats the ball away, as if it were struck with a material agent. If the sun's light be filtered through coloured glasses before concentrating them on the pith ball, the action is slightly diminished. Passing the light through two very clear plates of alum with parallel sides, and having an aggregate thickness of 8 millims., had but little action.

58. A beam of sunlight was passed through a prism *a* (fig. 6), and the spectrum was projected horizontally on to a screen (*b*) 18 feet off. In front of the screen, a little below it, was arranged the balance-tube *c*, having fixed above it a lens *d*, so that one of the pith balls was in the focus of the lens. A small right-angled prism (*e*) was then held in the different parts of the spectrum, so as to reflect any desired ray on to the lens and concentrate it on to the pith ball. By turning the right-angled prism sideways, the ray could be thrown off and on the ball, and the action readily noted. In the ultra-violet rays the repellent action was slight; the effect increased as I made the reflecting prism traverse the spectrum from the violet to the red. The maximum action was in the extreme visible red, and it gradually faded away as the invisible rays beyond the red were reflected down. An appreciable action of repulsion was, however, observed a full half spectrum in length below the least refrangible visible rays. The plates of alum, interposed in the path of the rays, cut off a small portion only of their action.

[To be continued.]

THE CHEMICAL NEWS.

Vol. XXXI. No. 790.

ON

ATTRACTION AND REPULSION RESULTING FROM RADIATION.*

By WILLIAM CROOKES, F.R.S., &c.

(Continued from page 13.)

32. When the balance was in air of ordinary density, and the hot body was placed *above* the pith ball in the position *a* (see fig. 2), it will be remembered that the action was to cause the ball to rise: the rising was, however, less decided than when the heat was applied below (27, 29). On re-exhausting the balance-tube and taking a series of observations, placing the hot bulb above the pith ball in the position *a* (fig. 2), instead of below it, the ascending tendency of the pith got less and less. Several millimetres below the previously ascertained point of neutrality the hot bulb at *a* ceased to exert an action, and marked, being exactly opposite but equal to the action of the bulb of hot water.

34. In trying some of these experiments in a Sprengel vacuum an action was noticed which led me to think that some of these movements might be due to electricity. When a hot glass rod is held motionless against the lower side of the exhausted tube, the repulsion of the pith ball takes place in a perfectly regular manner; but if the glass rod has been passed once or twice through the fingers, or if it is rubbed a few times sideways along the exhausted tube, the beam immediately moves about in a very irregular manner, sometimes being repelled from and at others attracted to the side of the tube, where it sticks until the electrical excitement subsides. When the finger is rubbed against the exhausted glass tube, the same electrical interference takes place; attractions and repulsions occur by fits and starts, the pith sticks to the tube, and does not regain its ordinary state for some hours. When a small spirit-flame is passed beneath the pith end of the balance in the vacuum, a similar but much fainter electrical effect is noticed. This, however, is not sufficient to interfere with the repulsion due to radiation unless the vacuum is very good and free from aqueous vapour.

35. The end of a glass beam in a Sprengel vacuum was found to be attracted by either pole of an induction-coil, when the other pole was not well insulated.

Fig. 4.

Fig. 4A.

Fig. 4B.

when the neutral point was exceeded by some millimetres I could still detect no movement. However, at a millims. below a vacuum, I detected a tendency of the pith to sink when the experiment was tried, and in a good Sprengel vacuum there was an unmistakable repulsion exerted between the two bodies, the pith sinking in obedience to the radiation from above almost as strongly as it rose when the heat was applied beneath.

33. I now wish to ascertain the effect of cold on the balance pith balls, and for this purpose a lump of ice was employed.

The experiments were first tried with the balance-tube full of air, cold being applied either above or below the pith ball; a lump of ice generally produced an upward movement of the pith, but it was very faint, and sometimes the motion appeared to be in the opposite direction. It was evident that the true action of a cold body, whatever it might be, was here masked by currents of air; and I therefore exhausted the apparatus and tried the effect of ice at the previously ascertained neutral point, viz., at about 7 millims. below the vacuum. It was absolutely inert. I then carried the exhaustion to the fullest extent, testing the balance with ice during its progress. As the gauge approached nearer and nearer to the height of the barometer, the ice commenced to attract the pith; and at last, when the gauge and barometer were level, the attraction of the ice, whether applied above or below, was very

To ascertain whether electricity exerted any special action in the ordinary repulsions in vacuum, the following experiments were tried:—

36. A straw beam with pith extremities was enclosed in a tube (24) and exhausted to the full power of the Sprengel pump. After adjustment by heat, till it was in equilibrium and very delicate to slight radiation, it was re-exhausted and hermetically sealed up. The tube was then completely surrounded with wet blotting-paper, with the exception of a small aperture through which the movement of the beam could be observed; the blotting-paper was connected to earth by a wire soldered on to a gas-pipe.

On bringing a piece of warm copper beneath the pith ball, it rose as readily as if the outside of the tube had been dry and insulated. The finger moistened with warm water also repelled the pith; and when cooled with melting ice, and then applied dripping wet either above or below the pith ball, there was attraction. The same result, but more strongly marked, took place when a piece of ice was used instead of the cold finger.

A straw beam furnished with brass balls at each end* was suspended in the usual manner on a double-pointed needle; and the brass balls and needle were placed in metallic connexion by means of a very fine platinum wire. The needle did not rest on the sides of the glass

* From the *Philosophical Transactions of the Royal Society of London*, vol. clxiv., par. 2.

* Preliminary experiments showed me that the brass balls on the straw beam acted in every respect the same as the pith balls, with regard to hot and cold bodies externally applied, both at ordinary pressures and in a vacuum; but they moved in a more sluggish manner.

70, Lansdowne Place, Brighton, June 13, 1876.

THE ORIGIN OF MOTION.

To the Editor of Engineering.

Sir,—Your contributor, the writer of the articles on "The Origin of Motion," told you in his last letter, written in reply to two previous letters of mine on this subject, that he has some difficulty in imagining that I can be serious in supposing that the molecular vibrations of a piece of card have anything to do with its attraction by a vibrating tuning-fork. To him there appears to be something supremely ridiculous in the supposition that the vibration of the molecules of the card can be the cause of anything. He gave me credit for more sense than is implied in asking him to criticise "such a theory" as mine. "When we talk," he says, "of the effect produced by a vibrating tuning-fork . . . we allude to the effect produced on the air by the mass vibrations of the fork, not considering at all the vibrations of the molecules of the fork"—meaning, I suppose, that if the fork itself did not vibrate it could not by any possibility attract a suspended card.

Now, without wishing for a moment to question your contributor's right to refuse to criticise anything advanced by me, I may as well here point out—I ought to have done it before—that the molecular vibrations of a tuning-fork are not quite so insignificant as your contributor would have us believe. The fact is, a non-vibrating fork is as capable of attracting bodies suspended near it as a vibrating one is. We have only to increase the energy of the molecular vibrations of a non-vibrating fork, in other words, to raise its temperature, and it exerts an attractive influence upon pith balls, &c., probably as marked as is the influence exerted by a tuning-fork in vibration upon a suspended card, as Mr. Crookes long ago pointed out. A heated tuning-fork *a*, not in vibration, would, according to Mr. Crookes' experiments, attract another tuning-fork *b*, at ordinary temperature, suspended near it. That is, the vibration of the molecules forming *a*'s surfaces influences the surrounding air molecules in such a way as to cause the fork *b* to approach *a*, precisely as it would do if the fork *a* were itself in vibration. In fact the two cases seem to me to be precisely alike; and I would explain the attraction exerted by a *heated* tuning-fork in exactly the same manner as I have explained in my former letters (and too many times to render a repetition necessary), the attraction exerted by a vibrating one. *The molecules forming the surfaces of the fork b* have, in this case, in my opinion, as much to do with its movement towards *a*, as the molecules *forming a's surfaces* have to do with the matter, that is, their vibration has everything to do with it. And I submit that there is nothing whatever in this common-sense view to justify the use of such contemptuous phrases as "such a theory" which your contributor makes use of.

Your contributor has of course a perfect right, as well as my full permission, to refuse to criticise my views, but he has no right whatever to make it appear that he knows more about my opinions than I know myself, and to attribute to me opinions which I have again and again emphatically stated that I do not hold. Your contributor is content, he tells you, to leave my theory to the criticism of others. Then why not leave the theory alone? If he will not or cannot urge any valid objection against my theory that the molecular vibrations of the card are the cause of its attraction by a vibrating tuning-fork, why on earth does he raise objections against nobody's theory that the attraction of the card is due to the reaction of the card itself upon the medium, a theory which implies, as he says, that the card could not be attracted by the fork unless it (the card) vibrated; or, as he puts it in another place, which assumes that a body in order to be attracted must *vibrate*? I suppose that some careless expression of mine was the original cause of this misunderstanding, but surely I stated emphatically enough in my last letter that the above was not the theory that I wished your contributor to criticise. My views may be altogether nonsensical, may not even be worth discussing; but if they are so very absurd, why endeavour to make them more so by misstating them?

I may here remark (though I do so with no hope of reversing the decision of your contributor to leave my theory to the criticism of others) that this very theory which is now deemed so absurd, I submitted some time since to the notice of an eminent professor of physics, a F.R.S., and a contributor to the *Philosophical Magazine*, and that, in a very courteous and even kindly letter which I received in reply, he invited me to give an account of my theory to the —— Society, offering at the same time to give me every assistance in his power in the way of preparing diagrams, &c. I may also remark that he assured me that individually he "believed my ideas to possess very great merit," that after being read my paper would be considered with reference to its publication in the *Transactions* of the Society and in the *Philosophical Magazine*. And he even went so far as to promise to get some one to read my paper before the said society, adding that if he could not do so

10

he would *read it himself*. All this commotion caused by a theory which your contributor is half inclined to regard as a sort of joke! Surely I could not be serious when I asked him to criticise "such a theory."

Perhaps your contributor's object in disposing of my theory in this off-hand manner was to induce me to follow his example by leaving *his* theory "to the criticism of others." If so, he shall not be disappointed. Seeing that your contributor emphatically refuses to criticise my theory, and that he seems disposed to take but the least possible notice of the objections that I ventured to urge against his own; and, moreover, seeing that it is eminently desirable that this controversy should for your readers' sake, have some definite result, I ask your permission to appeal to those of your readers and correspondents who interest themselves in the subject, and to solicit their opinion on the various points in dispute. I have scarcely anything to say, in addition to what I have already stated in my former letters, either in support of my own views or in support of my objections against those of your contributor. But the subject has been so confused by your contributor's having misstated my theory and my objections to his own (I am sure it cannot be said that I have erred in this respect) that a concise statement of the various issues between us may perhaps assist the jury to whom I appeal, in arriving at a unanimous verdict, which I submit cannot fail to be in every instance in my favour and against your contributor.

Although a great deal of our correspondence has been taken up in dealing with tuning-forks and cards, I believe I am not far wrong when I say that the profoundly mysterious, yet provokingly simple, problem which is the real one to be solved is this: Every molecule of every portion of what for distinction's sake may be termed *gross* matter, moves, or tends to move, at every instant as if it were attracted by every other molecule with a force varying with the inverse square of the distance between the molecules. A molecule at the centre of the sun, for instance, attracts, and is attracted by, a molecule at the centre of the earth. Your contributor and myself both claim to be able to present the world for the first time in history, with a satisfactory explanation of how the thing is done. This is rather presumptuous on our part no doubt; but fools, you know, rush in where angels fear to tread. Perhaps, nay probably, both our theories may be false. No matter. Repeated attempts of this sort may at last convince the "angels" that their fears are quite groundless, and we may thus aid, though indirectly, in bringing about a state of things more creditable to science than obtains at present.

On the one hand, your contributor is of opinion that the central molecule of the sun attracts the central molecule of the earth by means of an elastic medium called ether, which is composed of particles that are rapidly moving in all directions. Our two molecules are themselves in rapid vibratory motion and thus emit waves in all directions. Waves are reflected to and fro between the two molecules, and owing to this reflection of waves the particles of ether composing the column intercepted between the two molecules are continually receiving increments of energy, in consequence of which the column expands and becomes rarefied, and the pressure of the ether in the column becomes diminished. Besides this, owing again to the reflection of waves, the column of ether is thrown into *stationary* vibration. It becomes broken up into segments, which segments vibrate radially outwards, that is, laterally, and thus tend to expand the column radially, to rarefy the axis of the column, and to diminish ethereal pressure at its axis. But stationary vibration is also caused in another way. When one molecule advances towards the other it *bulges* the column radially, the converse taking place by the recession of the molecule, and thus a radial (and longitudinal?) vibration of the ether column about a central axis is set up and the column expands; the pressure in the column, owing to the combined influence of these causes, diminishes; and the pressure upon the remote sides of the two molecules urges them together.

Against this elaborate theory it is surely sufficient to object that the said intercepted column of ether is nearly a hundred millions of miles in length, whilst its diameter may be estimated by keeping in mind that (according to Sir W. Thomson) if we were to magnify a drop of water to the size of the earth, the coarseness of the graining of it would be something between that of cricket-balls and small shot.

I should, however, be content to stake my reputation (if I had any) upon the validity of any one of the following objections:

In the first place, the two vibrating molecules, by increasing the velocity of the particles of ether in the intercepted column, tend to increase and not to diminish the pressure in the column, for the motion of the particles of the ether is assumed by us both to be the sole cause of its pressure. No more conclusive demonstration of this proposition could be imagined than the following: Suppose that a column of ether exactly resembling in all respects the column actually intercepted between our two vibrating molecules were enclosed in an impenetrable tube. Your contributor insists that the pressure of the ether within the tube is less than the outside pressure. And so it might be as long as there were no communication between the ether within the tube and that outside. But directly we allow the ether in the tube to communicate freely with the rest of the medium, it is, I submit, absolutely impossible to give any reason why the inside pressure should not become immediately equal to the outside pressure, however much difference there may be between the density of the ether particles outside and the density of the other particles inside the tube. There is, you will perceive, a perfect parallel between this imaginary column and the column actually intercepted between our two vibrating molecules, for both columns communicate freely with the rest of the medium. Your contributor persists in ignoring this weighty objection. Until it is answered, I submit that the mere fact that the two molecules do approach each other is not sufficient to prove that their approach is due to an excess of ethereal pressure upon their two remote sides. The jury to whom I am now appealing will rightly demand something more from your contributor than the usual re-statement of his theory, or judgment will go against him in default.

In the next place, granting for the moment that by the reflection of waves between our two molecules, or by their bulging the intercepted column radially, or by any other means, the column is broken up into annular segments, which vibrate about a central axis (remember the length and diameter of the column), I contend that we have as yet no *vera causa* for the assumed diminution of pressure at the axis of the column. I do not deny that under the assumed conditions the column would tend to expand, but I assert that for this very reason the pressure at the axis would tend to increase and not diminish. In illustration of his position your contributor supposes that two elastic spheres are rebounding between two parallel planes in such a way that the two spheres strike each other at the middle point between the planes, and then rebound and strike the planes simultaneously, the spheres oscillating backwards and forwards. The spheres, he tells us, will exercise a pressure tending to propel the planes apart. Of course they would. But if the exterior surfaces of the two planes were subject to the pressure of the ether, and the interior surfaces merely to the pressure caused by the impact of the two spheres, they would not recede from each other, unless the pressure of the spheres were greater than the pressure of the ether. If this were the case they would recede from each other until the pressure due to the impact of the spheres had become exactly equal to the pressure of the ether upon their remote surfaces. The spheres would go on rebounding from each other and from the planes alternately, and the important point to be noted is this, they would rebound *from each other* with precisely the same force as they rebound from the two planes, so that if a third plane were placed parallel with the other two midway *between* them, the two spheres would rebound from the middle plane with exactly the same energy as they rebound with after striking the two outside planes. The application of which is obvious. The pressure of the ether at the axis of our imaginary column is, and would always remain in spite of any amount of "stationary vibration" of its imaginary annular segments, precisely equal to the pressure of the ether at every other part of the universe.

Thirdly, your contributor has entirely failed to grapple with the objection I raised against his theory on the ground that the so-called column of ether intercepted between our two molecules is only an imaginary one, seeing that (leaving out of consideration the by no means inconsiderable motion of our solar system through space) at least one of our molecules is moving round the other at a thousand miles per minute, so that no waves can possibly be reflected along our "column;" for by the time a wave has travelled from one molecule to the other, the first molecule is in quite a different part of space altogether from where it was when the wave first started on its immensely long journey; and by the time the wave is reflected back again (if it ever could be reflected, which is rather doubtful), our first molecule is still further removed from its former position. This objection is as yet unanswered, and I do not wonder that it is so. What your contributor says on this point falls quite wide of the mark. I have not (I am told) fully appreciated the facts of the case. I ought to have remembered that when a column of ether is in stationary vibration, it is broken up into longitudinal segments, and that the wave reflected towards one molecule is not reflected from the other molecule, but only from the immediately adjacent longitudinal segment. But I thought we were told, and on looking back I find we *were* told, that *the mutual reflection of waves between the opposed pair of vibrating molecules is the condition required* to throw the intercepted column into stationary vibration, and that *no effect* at all would be produced unless the waves were reflected. My objection therefore goes to the very root of the matter, for even if it were true that your contributor has met the difficulty, provided I admit that there is no necessity that waves ought to be continually reflected, the fact would still remain that I have proved past all contradiction (or at least according to your contributor's own showing) that no effect at all could be produced, because no breaking up of the column into longitudinal segments ever has or ever can take place, for this, we are told, entirely depends upon the reflection of waves between the two molecules within the intercepted column. Your contributor in his letter of May 12, used the expression "reflection of waves between the two molecules," or something equivalent to it, about, if not exactly, *thirteen times*. Had he but kept in mind the motion of our molecules through the ether, which comes to precisely the same thing as *the motion of the ether past the molecules*, the expression would never have been used *once* in connexion with a theory of gravitation.

Fourthly and lastly (but I am afraid the jury will think that I am breaking a butterfly upon the wheel) we have as yet not a syllable in answer to my objection that the column intercepted between the two molecules under consideration (the central molecule of the sun and the central molecule of the earth) is to a very great extent not composed of ether particles at all, but of molecules of ordinary matter. Even if there were one molecule in the intercepted column it would prevent any wave from passing from one molecule to the other, but there are more than one. Thousands of miles of the so-called column are thickly studded with molecules, each one of which is a fatal stumbling-block in the way of your contributor's obtaining a favourable verdict from the jury of impartial inquirers to whom I am now appealing.

This, then, is my case against the theory of gravitation advanced by your contributor, and I venture to anticipate a unanimous and decisive verdict in my favour upon each of the above grounds. With regard to my own theory, seeing that your contributor declines to raise any objection

11

against "such a theory," I have of course none to answer. I really cannot afford time to dispose of the ingenious difficulties urged by your contributor against the theory which he has been pleased to associate with my name, so that I have only to refer every one who wishes to see the clearest statement that I know how to write of the theory which I shall continue to advocate so long as I believe it to be true, to my letter on the "Origin of Motion" which you were good enough to publish in ENGINEERING of May 26. I must conclude my remarks in another letter, meanwhile I remain,

Faithfully yours,
THOMAS INWOOD POLLARD.

SCIENTIFIC NEWS.

Feb 1876

WHATEVER may be the ultimate outcome of Mr. Crookes' scientific toy, the radiometer, it cannot be doubted that it is a very important discovery. It is natural for its inventor to be sanguine in estimating its future; and as we never know what to-morrow may bring forth, it is possible that the radiometer may find some useful employment in one or other of the several practical applications which Mr. Crookes mentioned in his recent lecture at the London Institution. He suggests that the torsion balance which he has used for testing the amount of action of the radiometer should be employed for estimating the quality of our gas supply. The standard "candle" would first be tested, and then a comparison made between the gas and the candle, the slightest motion of the balance being easily recorded. Mr. Crookes has arranged the rotating wires and pith discs in such a manner that they carry with them a small magnet, which causes another magnet to oscillate, as the two poles of the first are respectively presented to it. The oscillating magnet makes and breaks an electric circuit, with which a Morse recorder is connected. By this means an automatic counter is constructed, which registers the number of revolutions made by the vanes, and so records the amount of light falling on the radiometer. Gossip is busy with these ideas, and it is stated that Mr. Crookes has "perfected" the apparatus for recording the quantity of light, and has named it the lucometer. Mr. Crookes was to read a paper last night, at the Royal Society, in the course of which it is stated that he will show that his radiometer is not only capable of acting as a photometer but as a photo-barometer, or light-weigher. We can only hope there is no disappointment in store for us.

[illegible]—The Radiometer.—This is a subject on which much has been written, and many singular views advanced. It was at one time almost supposed that the undulatory theory of light would have to be altered or abandoned; and an extraordinary statement as to the number of tons pressure on the earth, owing to the sun's rays, appeared, and was duly marvelled at by outsiders, and marvellously laughed at by others. The correct explanation of the instrument seems to be as follows:—The vacuum not being absolute (not even so perfect as it could be made with a good Sprengel pump), there is, therefore, some air in the bulb with the vanes. Any heat or light falling upon the dark side is absorbed, and heats in a very slight degree the air adjacent. This expands, and in so doing gives the vane a push, causing the rotation observed. The instrument will not act if the exhaustion be pushed too far. It seems there must be just sufficient air to give the requisite push, but not enough to clog the vanes.—DEACON, Lorain.

THE MECHANICAL ACTION OF LIGHT.*

By William Crookes, F.R.S.

(Concluded from page 174.)

The advantage of a glass-thread suspension is that the beam always comes back to its original position.

An instrument of this sort, perfectly exhausted and then sealed off, is shown at work in Fig. 5. It has pith plates at the extremities of the torsion beam. A ray of light from the lamp is thrown on to the central mirror, and thence reflected on to the graduated scale. The approach of a finger to either extremity of the beam causes the luminous index to travel several inches, showing repulsion. A piece of ice brought near causes the spot of light to travel as much in the opposite direction. In order to insure the luminous index coming accurately back to zero, extreme precautions must be taken to keep all extraneous radiation from acting on the torsion balance. The whole apparatus is closely packed round with a layer of cotton-wool about 6in. thick, and outside this is arranged a double row of Winchester quart bottles filled with water, spaces only being left for the radiation to fall on the balance and for the index ray of light to get to and from the mirror.

However much the results may vary when the vacuum is imperfect, with an apparatus of this kind they always agree among themselves when the residual gas is reduced to the minimum possible; and it is of no consequence what this residual gas is. Thus, starting with the apparatus full of various vapours and gases, such as air, carbonic acid, water, iodine, hydrogen, ammonia, &c., there is not found at the highest rarefaction, any difference in the results which can be traced to the residual gas. A hydrogen vacuum appears the same as a water or an iodine vacuum.

The neutral point for a thin surface of pith being low, and that for a moderately thick piece of platinum being high, it follows that at a rarefaction intermediate between these two points pith will be repelled, and that platinum will be attracted by the same beam of radiation. This has been proved experimentally. An apparatus showing simultaneous attraction and repulsion by the same ray of light is illustrated in Fig. 6.

The pieces $f\ g$ on the end of one beam consist of platinum foil exposing a square centimetre of surface, whilst the extremities $f'\ g'$ on the other beam consist of pith plates of the same size. A wide beam of radiation thrown in the centre of the tube on to the plates $g\ g'$ causes g to be attracted and f' to be repelled, as shown by the light reflected from the mirror $c\ c'$. The atmospheric pressure in the apparatus is equal to about 40mm. of mercury.

In a torsion apparatus similar to the one shown in Figs. 4 and 5, I have submitted variously coloured discs to the action of the different rays of the spectrum. The most striking results, as yet, have been obtained when the different rays of the spectrum were thrown on white and on black surfaces. The result was to show a decided difference between the action of light and of radiant heat. At the highest exhaustions dark heat from boiling water acts almost equally on white pith and on pith coated with lamp-black, repelling either with about the same force. The action of the luminous rays, however, is different. These repel the black surface more energetically than they do the white surface, and, consequently, if in such an apparatus as is shown at Fig. 4, one disc of pith is white and the other is black, an exposure of both of them to light of the same intensity will cause the torsion thread to twist round, owing to the difference of repulsion exerted on the black and the white surface. If, in the bulb apparatus shown in Fig. 3, the halves of the pith bar are alternately white and lamp-blacked, this differential action will produce rapid rotation in one direction, which keeps up until stopped by the torsion of the suspending fibre.

Taking advantage of this fact I have constructed an instrument which I have called the Radiometer, shown in section and plan at Figs. 7 and 8. It consists of four arms, of some light material, suspended on a hard steel point resting in a jewel cup, so that the arms are able to revolve horizontally upon the centre pivot, in the same manner as the arms of Dr. Robinson's anemometer revolve. To the extremity of each arm is fastened a thin disc of pith, white on one side and lamp-blacked on the other, the black surfaces of all the discs facing the same way. The whole is enclosed in a thin glass globe, which is then exhausted to the highest attainable point and hermetically sealed.

The arms of this instrument rotate with more or less velocity under the action of radiation, the rapidity of revolution being directly proportional to the intensity of the incident rays. Placed in the sun or exposed to the light of burning magnesium, the rapidity is so great that the separate discs are lost in a circle of light. Exposed to a candle 20 in. off another instrument gave one revolution in 182 seconds; with the same candle placed at a distance of 10 in. off the result is one revolution in 45 seconds; and at 5 in. off one revolution was given in 11 seconds. Thus it is seen that the mechanical action of radiation is inversely proportional to the square of the distance. At the same distance two candles give exactly double, and three candles give three times, the velocity given by one candle, and so on up to twenty-four candles. A small radiometer was found to revolve at the velocities shown in the following Table, when exposed to the radiation of a standard candle 5 in. off.

Time required for One Revolution.

Source of Radiation.	Time in Seconds.
Candle, 5 in. off, behind green glass	... 40
" 5 " " blue "	... 38
" 5 " " purple "	... 28
" 5 " " orange "	... 26
" 5 " " yellow "	... 21
" 5 " " light red "	... 20

[Diff]used daylight the velocity was one revolution in [...] seconds to 2.3 seconds, according to the intensity [of the in]cident rays. In full sunshine, at 10 a.m., it revolved once in 0.3 second, and at 2 p.m. once in [...] second.

When heat is cut off by allowing the radiation to pass through a thick plate of alum, the velocity of rotation is somewhat slower, and when only dark heat is allowed to fall on the arms (as from a vessel of boiling water) [no] indications whatever is produced.

In all respects, therefore, it is seen that the radiometer gives indications in strict accordance with theory.

Several radiometers, of various constructions [...] details, but all depending on the above-named [...] have been exhibited at the Royal Society, wh[ere their] novelty and unexpected indications excited a co[nsiderable] amount of interest.

This form of instrument is of too recent a constr[uction for] me to be able to do more than draw brief attention [to some] of the many uses for which it is applicable.

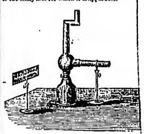

Fig. 5.

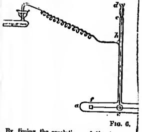

Fig. 6.

By timing the revolutions of the instrument exposed direct to a source of light—a candle, [for in]stance—the total radiation is measured. If a [plate] of alum is now interposed, the influence of [dark heat is] almost entirely cut off, the velocity becomes proport[ionately] less, and the instrument becomes a photometer. [By this] means photometry becomes much simplified; [lights the] most diverse may readily be compared between the[mselves] or with other sources of light; a "standard cand[le" may] now be defined as one which at x inches off can [cause a] radiometer to perform y revolutions per minute, th[e values] of x and y having previously been determined by com[parison] with some ascertained standard; and a statement[, that a] gaslight is equal to so many candles may, with more ac[curacy,] be replaced by saying that it produces so many revol[utions.]

To photographers the radiometer will be invaluab[le. As] it will revolve behind the orange-coloured glass used [for ad]mitting light into the so-called dark room, it is only [neces]sary to place one of these instruments in the win[dow to] enable the operator to see whether the light enter[ing the] room is likely to injure the sensitive surfaces [ex]posed; thus, having ascertained by experience [that his] plates are fogged, or his paper injured, when the revo[lutions] exceed, say, ten a minute, he will take care to draw [an] extra blind when the revolutions approach that n[umber.] Still more useful will the radiometer be in the photo[graphic] gallery. Placing an instrument near the sitter at [the com]mencement of the day's operations, it is found that [to ob]tain a good negative, the lens must be uncovered [for] a particular number of seconds—but during the t[ime re]quired for the radiometer to make, say, twenty revo[lutions.] For the remainder of the day, therefore, assum[ing the] chemicals not to vary, the operator need not troubl[e him]self about the variation of light; all he has to do is t[o watch] the radiometer, and expose for twenty revolutions, [and his] negatives will be of the same quality,* although at [one time] it may have taken five minutes, and at another [a few] seconds, to perform the allotted number.

I have long been experimenting in the endeavour [to trace] some connexion between the movements of attrac[tion and] repulsion above alluded to, and the action of grav[itation in] Cavendish's celebrated experiment. The investigati[on is not] sufficiently advanced to justify further details, but [I give] here an outline of one of the results.

I find that a heavy metallic mass, [...] brought [...]

THE ATTRACTION AND REPULSION CAUSED BY THE RADIATION OF HEAT.—40.

Apparently Mr. Crookes does not understand the nature of the forces which I have shown to result from the communication of heat between a gas and a surface; otherwise he would not bring forward as conclusive against the supposition that the phenomena which he has discovered are due to these forces, experiments which show entirely the other way. As I have previously explained, it follows as a direct result of the kinetic theory of gas, that if such forces as I have supposed exist for a certain tension of the gas surrounding the surface, they will not be diminished by diminishing the tension of the gas; and consequently no amount of pumping would destroy such forces where they once existed. Whereas the smaller the tension of the gas the freer the surface will be to move, and the less its motion would be opposed by convection currents; hence, on the supposition that the motion is due to these forces, the only effect of improving the vacuum would be to intensify the action. And this being the case, it is clear that Mr. Crookes' experiments, in which he finds that the action still remains in the most perfect vacuum which he has obtained, tend to support and not to upset my conclusion that the actions are due to these forces. The fact that Mr. Crookes finds it impossible to conceive this only shows, as I have said, that he does not comprehend the nature of the forces; for it certainly presents no greater difficulty than the fact that the velocity of sound is independent of the tension of the gas through which it is transmitted.

Mr. Crookes still appears to think that I attribute these forces solely to the presence of condensable vapour. It is true that the title of my first paper might have led him into this error had he read no farther; but both in that paper and in a letter to the *Philosophical Magazine* for November, 1874, it is clearly shown that this is not the case.

I am in hopes that ere long we may hear something on this subject from Professor Maxwell, who probably knows more about the kinetic theory of gases than anyone else. If I am right, these experiments afford a direct proof of the truth of this theory; and as far as I know, this is the only direct proof that has ever been obtained. I do not mean to say that this is the most conclusive proof, but the most direct, or, to quote a remark of Dr. Balfour Stewart, "These experiments stand in much the same relation to the kinetic theory of gases that Foucault's pendulum occupied with regard to the rotation of the earth." No one can admire more than I do the experimental skill with which Mr. Crookes has brought the phenomena to light; nor can I see, should it turn out as I maintain, that they have led to the discovery of a law of nature, that this will detract from their importance, even if they lose somewhat in general interest from the breaking up of the halo of mystery with which they have hitherto been surrounded.

Osborne Reynolds.

Owen's College, May 24. 1875

40.—From the *Engineer.*

[2000.]—Vacuum Tube.—The essentials for making vacuum tubes are, first, a good air-pump; second, a Bunsen's burner with bellows for blast; and, third, but not least, practical acquaintance with glass-blowing and manipulation. The cost of the apparatus requisite to obtain good tubes is beyond the limits of ordinary experimentalists. Of course you can make a vacuum tube out of a narrow test tube. All that has to be done is to exhaust the tube and hermetically seal both ends, having first inserted platinum terminals; but then, although a vacuum tube, it would hardly deserve that appellation. There is so much, I might add more, trouble in making small vacuum tubes (good ones, I mean) than large ones; and, considering that your query refers to small ones, I must really recommend you to purchase them, instead of attempting to make them yourself. Small ones can be purchased from 1s. 6d. each. I have watched the men making these cheap ones, and have been amazed at the neatness and cleverness requisite for the manufacture of a well-proportioned tube. This could only be obtained after years of practical work.—W. J. Lancaster.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences. No. 17, October 25, 1875.

New Spectro-Electric Tube (Modification of the Fulgurator).—MM. B. Delachanal and A. Mermet.—This tube is said to possess the following advantages:—Fixity of the spark, permitting a prolonged observation of the spectra; suppression of the meniscus, and consequently of the absorptions which it produces, and which partially hide the spark; removal of the electrodes into a special tube, which preserves the instrument from corrosive projections; possibility of collecting the total of the substance examined; possibility of forming a collection of spectroscopic tubes, containing permanently the solutions of various substances, and allowing of rapid demonstrations and comparisons. The description of the instrument would be unintelligible without the accompanying illustrations.

RADIOMETER—OXYGEN—"NONSENSE."

E. M. Feb. 76

[10125.]—I am glad "H. P. A." has raised a discussion concerning that curious instrument, the radiometer, and I think that farther experiment with it cannot fail to do good. However, I believe even Mr. Crookes himself, after several years' work at the subject, is unable to enunciate a theory which satisfactorily accounts for all the effects observed. Under such circumstances any theorising on the subject must be conducted with great caution.

I see "H. P. A." has twice referred to my condemnation of an explanation (on quite a different subject) by a well-known correspondent as "nonsense," and "H. P. A." expresses a hope that I shall not "see fit to designate his experiments as nonsense." Now, the observer who fairly states what he has observed can never be accused of talking nonsense. At the worst he can but have observed incorrectly, which has occurred to our best experimentalists, but, as long as he honestly states his belief, he is secure from criticism. When Mr. Lancaster made the remarkable statement that oxygen and hydrogen were consumed in the lime-light in the proportion O_2H_2, I asked, with all respect, if he could account for consumption in such anomalous proportion. Mr. L. ignored my question entirely, and when I again referred to the subject, after many months' interval, told me he could give no explanation of the fact. Still sceptical of the accuracy of his observation, I asked him to state his method of measurement, and was met by a flat refusal. As it turns out, Mr. Lancaster's observation is substantially correct, and I have never denied the truth of it. I was certainly very sceptical of his accuracy of observation, and pointed out the reason of my doubt. As it is, the anomaly remains quite unaccounted for, and certainly deserves further attention. Now, to have called Mr. L.'s statement "nonsense"—however astonishing it might be—would have been entirely out of place; but I contend that the expression was completely justified when Mr. Lancaster ventilated an original *theory* which was not even supported by the facts known to him, and which showed him to be but very imperfectly acquainted with the subject upon which he was undertaking to give information. By all means let correspondents ask for information, and state their views upon the subjects on which they write, but they should scarcely be permitted to give erroneous explanations on well-known subjects without being checked. Besides, it appears to be forgotten that I expressed my opinion that Mr. L.'s *theory* was "nonsense" in direct reply to his request to be informed whether I thought it *was* "nonsense;" and I stated at the time that I should not have used the term had he not specially asked if I thought it applicable to his writing.

Correspondents who write merely under initials, instead of employing a *nom de plume*, like "Sigma" and "Helveticus," suffer from a want of recognition as individuals. On this account "H. P. A.'s" contributions are not held so clearly in our minds as could be wished, but, as far as I am aware, "H. P. A." only writes on subjects he understands, and does not venture to lay down the law on questions with which his acquaintance is but slight. In

[...] can never fear being accused of talking "nonsense," either by me or any one else. [...] Mr. Lancaster [...] "nonsense" [...] Mr. Lancaster's error [...] with his discovery [...] English Mechanic.

Action of Magnets upon Rarefied Gases Enclosed in Capillary Tubes, and Illuminated by an Induced Current.—M. J. Chautard.—The spectral modifications produced by the action of magnets upon the induction light traversing rarefied gases are subject to very complex laws. The most striking result is an increase of resistance on the part of the induced current under the influence of the magnet. As long as the magnet is inactive the light circulates uniformly in the two tubes. It is suddenly arrested in the shorter and narrower tube at the moment when this is submitted to the action of the magnet. The effect may be produced with chlorine, iodine, sulphur, and selenium.

Magnetic Action on the Rarefied Gases of Geissler's Tubes.—M. J. Chautard.—The author states that it is perfectly well known that gases, and even metallic vapors, present spectra which differ according to the conditions in which they are accidentally placed, among which are temperature, pressure, and the combinations in which the substances occur. The experiments which he has made enable him to add to these modifying causes the action of a powerful electro-magnet. He insists that every spectroscopic observer, before attempting to calculate the numerical results of his experiments, should first determine his peculiar personal error.

ON REPULSION RESULTING FROM RADIATION. INFLUENCE OF THE RESIDUAL GAS.*

(Preliminary Notice.)

By WILLIAM CROOKES, F.R.S., &c.

I have recently been engaged in experiments which are likely to throw much light on some obscure points in the theory of the repulsion resulting from radiation. In these I have been materially assisted by Prof. Stokes, both in original suggestions and in the mathematical formulæ necessary for the reduction of the results. Being prevented by other work from completing the experiments sufficiently to bring them before the Royal Society prior to the close of the session, I have thought that it might be of interest were I to publish a short abstract of the principal results I have obtained, reserving the details until they are ready to be brought forward in a more complete form.

In the early days of this research, when it was found that no movement took place until the vacuum was so good as to be almost beyond the powers of an ordinary air-pump to produce, and that as the vacuum got more and more nearly absolute so the force increased in power, it was justifiable to assume that the action would still take place when the minute trace of residual gas which theoretical reasoning proved to be present was removed. The first and most obvious explanation therefore was that the repulsive force was directly due to radiation. Further consideration, however, showed that the very best vacuum which I had succeeded in producing might contain enough matter to offer considerable resistance to motion. I have already pointed out that in some experiments, where the rarefaction was pushed to a very high point, the torsion beam appeared to be swinging in a viscous fluid (194), and this at once led me to think that the repulsion caused by radiation was indirectly due to a difference of thermometric heat between the black and white surfaces of the moving body (195), and that it might be due to a secondary action on the residual gas.

On April 5, 1876, I exhibited, at the *Soirée* of the Royal Society, an instrument which proved the presence of residual gas in a radiometer which had been exhausted to a very high point of sensitiveness. A small piece of pith was suspended to one end of a cocoon fibre, the other end being attached to a fragment of steel. An external magnet held the steel to the inner side of the glass globe, the pith then hanging down like a pendulum, about a millimetre from the rotating vanes of the radiometer. By placing a candle at different distances off, any desired velocity, up to several hundreds per minute, could be imparted to the fly of the radiometer. Scarcely any movement of the pendulum was produced when the rotation was very rapid; but on removing the candle, and letting the rotation die out, at one particular velocity the pendulum set up a considerable movement. Prof. Stokes suggested (and, in fact, tried the experiment at the time) that the distance of the candle should be so adjusted that the permanent rate of rotation should be the critical one for synchronism corresponding to the rate at which one arm of the fly passed for each complete oscillation. In this way the pendulum was kept for some time swinging with regularity through a large arc.

This instrument proved that, at a rarefaction so high that the residual gas was a non-conductor of an induction current, there was enough matter present to produce motion, and therefore to offer resistance to motion. That the residual gas was something more than an accidental accompaniment of the phenomena was rendered probable by the observations of Dr. Schuster, as well as by my own experiments on the movement of the floating glass case of a radiometer when the arms are fixed by a magnet.†

My first endeavour was to get some experimental means of discriminating between the viscosity of the minute quantity of residual gas and the other retarding forces, such as the friction of the needle-point on the glass cup when working with a radiometer, or the torsion of the glass fibre when a torsion-apparatus was used. A glass bulb is blown on the end of a glass tube, to the upper part of which a glass stopper is accurately fitted by grinding. To the lower part of the stopper a fine glass fibre is cemented, and to the end of this is attached a thin oblong plate of pith, which hangs suspended in the centre of the globe: a mirror is attached to the pith bar, which enables its movement to be observed on a graduated scale. The stopper is well lubricated with the burnt india-rubber which I have already found so useful in similar cases (207). The instrument is held upright by clamps, and is connected to the pump by a long spiral tube. The stopper is fixed rigidly in respect to space, and an arrangement is made by which the bulb can be rotated through a small angle. The pith plate, with mirror, being suspended from the stopper, the rotation of the bulb can only cause a motion of the pith through the intervention of the enclosed air. Were there no viscosity of the air, the pith would not move; but if there be viscosity, the pith will turn in the same direction as the bulb, though not to the same extent, and, after stopping the vessel, will oscillate backwards and forwards in decreasing arcs, presently settling in its old position relatively to space.

No good

It was suggested by Prof. Stokes that it would be desirable to register not merely the amplitude of the first swing, but the readings of the first five swings or so. This would afford a good value of the logarithmic decrement (the decrement per swing of the logarithm of the amplitude of the arcs), which is the constant most desirable to know. The logarithmic decrement will involve the viscosity of the glass fibre, but glass is so nearly perfectly elastic, and the fibre so very thin, that this will be practically insensible.

According to Prof. Clerk Maxwell the viscosity of a gas should be independent of its density; and the experiments with this apparatus have shown that this is practically correct, as the logarithmic decrement of the arc of the oscillation (a constant which may be taken as defining the viscosity of the gas) only slightly diminishes up to as high an exhaustion as I can conveniently attain—higher, indeed, than is necessary to produce repulsion by radiation.

I next endeavoured to measure, simultaneously with the logarithmic decrement of the arc of oscillation, the repulsive force produced by a candle at high degrees of exhaustion. The motion produced by the rotation of the bulb alone has the advantage of exhibiting palpably to the eye that there *is* a viscosity between the suspended body and the vessel; but once having ascertained that, and admitting that the logarithmic decrement of the arc of oscillation (when no candle is shining on the plate) is a measure of the viscosity, there is no further necessity to complicate the apparatus by having the ground and lubricated stopper. A movement of the whole vessel bodily through a small arc is equally effective for getting this logarithmic decrement; and the absence of the stopper enables me to have the whole apparatus sealed up in glass, and I can therefore experiment at higher rarefactions than would be possible when a lubricated stopper is present.

Radiometer of Mr. Crookes.—M. G. Govi.—The author cumbats the objection raised against his theory from the fact that a radiometer surrounded by a circle of lights does not come to a stop. He argues that in a circle of candles, where the intensity of the light varies without ceasing, and where currents of air may cool the small glass case irregularly, the point of thermic equilibrium, which would stop the rotation, would only be reached with great difficulty. He maintains that a uniform temperature ought to produce continual rotation as well as a continual access of light. He describes an experiment in which a very sensitive radiometer, with discs of aluminium polished on one side, and of mica blackened on the other, and placed in a cylinder of glass, into which the steam of boiling water was passed continuously, began to turn with great velocity, the aluminium sides foremost as soon as the steam had begun to raise the temperature of the case. By-and-bye, the temperature remaining invariable, the rotation slackened, and finally stopped as long as the heat was constant. When the access of the steam was cut off the radiometer began to turn in the contrary direction, and continued so for a long time. Any radiometer may be made to turn in this direction by plunging it into a vessel of cold water. It begins to move immediately, the blackened side of the discs foremost, and only stops after a certain time, *i.e.*, when a new state of thermic equilibrium has been reached. If the instrument is then taken out of the cold water it begins to turn in the same manner as if it had been exposed to light, even though it is all the time in the most profound darkness. If for the discs of aluminium and blackened mica we substitute a set of burnt mica, blackened on one side, the phenomena are complicated, whether because of the bad conductibility of the mica, or because at a certain temperature the nacreous surface of the mica absorbs much obscure heat, and gives off more gas than the blackened side. Thus, in the case heated to 100°, this radiometer turns regularly for a certain time with the nacreous surfaces foremost, then stopped, and began to turn in the contrary direction. The author then describes some unsuccessful attempts made to eliminate the gases adhering to the discs.

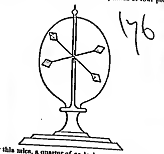
Explanation of the Movement of the Radiometer by the Aid of the Theory of Emission.—M. W. de Fonvielle.—The blank surface which reflects the light, and behaves like an elastic surface, ought to be more energetically repelled than the black if the luminous molecules act like masses striking the surfaces of the radiometer. But this principle supposes that the speed of the shock is not superior to the speed of the propagation of molecular movements, which latter is less than that of a ball proceeding from a revolver. This applies *a fortiori* to the shock produced by the luminous molecules, whose speed is a thousand times greater than that of a bullet. In this case, therefore, the absorbing or obscure surfaces should be repelled.

Radiometer of Mr. Crookes.—M. E. Ducretet.—The radiometer being exposed to ordinary daylight, its discs take a movement of direct rotation, the black surfaces being repelled. If ether is poured upon the case the movement is stopped, and then re-commences in an opposite direction. This reaction soon ceases, and we see the discs resume the original direct movement, in spite of the evaporation on the glass case, kept up by a gentle sprinkling with ether. At this moment the rotation becomes more rapid than at first, the evaporation seeming to act as if it were a source of heat, and yet the fall of temperature caused by the evaporation of the ether is very distinct. As soon as the application of ether ceases the movement resumes its normal speed, and remains direct. To repeat these experiments it is necessary to wait till the interior temperature of the radiometer has become equal to that of the surrounding air. The author has exposed a radiometer fixed in a dark place to the action of some tubes filled with phosphorescent powders, rendered very luminous by a previous exposure to the sun. There was no movement. The author is constructing a radiometer in which the reflecting surfaces are covered with very phosphorescent powders, whilst the other surfaces are blackened.

THE RADIOMETER.

The members of the Photographic Society of France were lately very much interested by the presentation of the "radiometer" of Mr. Crookes. Although this pretty little instrument has been the subject of much controversy in England and Germany, still it is very little known in France even at the present day. The radiometer presented to the Society was of the form and size of a large swan's egg, and made of blown glass. In the centre is a pedestal of the same substance, and rising half-way up the egg. Another pedestal descends from the top and meets the lower one to within about an eighth of an inch. The two ends of these pedestals are hollow for about a quarter of an inch; the pedestals are employed, the lower one to support, the upper one to hold a light steel axis, to which is attached a kind of windmill sail, made of four pieces

176



of very thin mica, a quarter of an inch square, and of exactly the same weight; one side of the mica is painted black and the other is silvered. This kind of four-sail mill is placed in perfect equilibrium between the two pedestals or pillars, a vacuum is then obtained, and, what is extraordinary, if the apparatus be placed in sunlight, it will revolve with astounding rapidity; if put in the shade, it will turn slowly; if in the dark, it will remain stationary. It might be supposed that the great stumbling-block to photographers was now removed, and that the actinic power of light could now be measured with precision, and that they would now be enabled to expose their models the exact length of time at any hour of the day without making a single error. Alas! it was soon discovered that not only light but heat had a great influence upon this instrument. Nevertheless, I am of opinion that we ought not to go to an excess in an opposite direction and cast it away as useless, because it does not fill up the conditions of superiority with which we were pleased at first to endow it in our enthusiasm; with a little patience, common sense, and a few experiments, the instrument even as it is would render great service to photographers. A cross, star, or other sign could be painted on one of its sails, and the instrument be fixed in a corner of the studio. Now, if a certain number of observations were made daily of the number of rotations per minute at a certain hour with the temperature at that moment, together with the time required for the exposure of the wet plate employed to make the portrait of the sitter, if all this were noted down carefully for a short time, the value of the instrument would soon become apparent, a table could then be drawn up for the time of exposure required at a certain temperature, the instrument making so many revolutions per minute.—*French Correspondence of the Philadelphia Photographer.*

Maximum of the Possible Repulsive Power of the Solar Rays.—M. G. A. Hirn.—The attention of the scientific world has been latterly drawn to the singular phenomena which Mr. Crookes has studied with the radiometer. The conclusion which has presented itself to the mind of many is that these phenomena are due to an impulsive action of the luminous rays, and that it is thus demonstrated that light is a movement of ponderable matter. Nevertheless, the phenomena discovered by Mr. Crookes have been elucidated, if not in their cause, still in their form and their starting-point. The ingenious counter-proof to which M. Arthur Schuster has submitted them places it beyond doubt that it is by no means the direct action of the rays emanating from the luminous source which determines the movement of the discs of the radiometer, but that the repulsive power here called into play has its seat in the walls of the transparent vessel which serves to contain the mill, and that this power is set in action by the pencil of rays directed upon the apparatus. As the true explanation of the totality of the phenomena has not yet been given, and as the hypothesis of the materiality and of the impulsive force of light will probably not soon be abandoned, the author thinks it useful to submit this hypothesis to the test of the method of successive elimination. Mr. Crookes has calculated the apparent repulsion exerted by the solar rays at 1 grm. per square metre. This pressure is more than one thousand times greater than the maximum value possible for reflecting bodies, and more than two thousand times superior to the maximum value possible for absorbing bodies. We may, then, affirm that the phenomena which Mr. Crookes has made known are nowise due to the effect of an impulsion of light, and do not imply the idea of mass of density as regards radiant light and heat. However carefully the vacuum in the vessel enclosing the radiometer or torsion balance may be made, there remain, nevertheless, quantities of gas or vapour relatively enormous. The maximum pressure which the solar radiation can exert upon a square metre of absorbing surface is 0·0004157 grm.: let us suppose that the discs of the radiometer are 10 square centimetres, the maximum pressure upon them will be 0·000004157 grm., or a little more than $\frac{1}{240000}$th of 1 grm. The slightest agitation of the small quantity of gas remaining in the apparatus will produce upon the radiometer pressure comparable to this. However transparent may be the glass case of the radiometer, it still absorbs a part of the calorific or luminous rays; one of its surfaces is heated more rapidly than the other. This inequality of temperature necessarily determines electric polarity, or the manifestation of static electricity. The vacuum, it is said, is so perfect that the electric spark cannot traverse the apparatus. But electric attractions and repulsions traverse the vacuum. However feeble may be this cause of attraction and repulsion, it may nevertheless have a considerable value in comparison with our maximum of 0·000004157 grm.

New Experimental Considerations on the Radiometer of Mr. Crookes.—M. A. Ledieu.—The author's experiments become less and less favourable to the theory of the apparatus based upon the movements of gases and vapours remaining within the glass case after the vacuum has been made. This theory, as we know, is subdivided into various doctrines, of which a very complete and lucid exposition has been given by M. Bertin in the June number of the *Annales de Chimie et de Physique.* The capital objection which mechanicians oppose to these different explanations is, they are all reduced to admit, that the radiometer is an instrument of reaction. But in such apparatus, having regard to the impossibility of the motive power being rapidly produced with a sufficiently constant intensity, there ensue merely rotations accompanied by retardations and bounds far from being reconcilable with the perfect regularity of the radiometer. Moreover, the theory in question expressly requires that there shall never be an equilibrium of temperature between the gas in the case and the discs of the radiometer. But how are we to admit that in every experiment this equilibrium is not ultimately established? Moreover, the rotation ought to stop at last instead of maintaining itself indefinitely at the same speed. The author then cites certain experiments difficult to explain by the supposed movement of gases in the interior of the apparatus. Thus the instrument was heated nearly to redness, when it commenced turning, but the rotation was sensibly accelerated by the momentary presence of a single flame, which joined its action to that of the radiant heat. An apparatus was constructed with discs exclusively polished. On throwing a pencil of solar rays upon one of the two hemispheres of the glass case a perfect rotation was obtained, without interruption, and as free and rapid as with an ordinary radiometer fully exposed to the light. The author bases his explanation of the phenomena upon a mechanical action of the "ether" perpendicular to the direction of its rays of propagation, and not in the same direction as these rays. This interpretation is calculated to calm the legitimate disquiet of the partisans of undulation. In Germany there is a leaning to an explanation based upon electricity. They rely upon the experiment that when a radiometer with discs exclusively polished, and where one of the hemispheres of the case is traversed by a continuous electric spark, the instrument takes a rapid rotation always opposite to the direction of the spark, this direction being understood according to the common convention. "In any case the radiometer of Mr. Crookes seems to us a serious instrument, and not a paradoxical apparatus destined to enjoy an ephemeral scientific repute and then to rank as a mere physical amusement. Its experimental study, pursued under all modifications and with an indefatigable perseverance, will certainly lead to important results as to the mechanical properties of the ether."

Process for the Manufacture of Soda from Seaweed by Endosmotic Lixiviation.—M. L. Herland.—The author gives the following reasons for the depressed state of the seaweed industry: the weed is collected indiscriminately without regard to its greater or less richness in iodides or other useful salts. The weed destined for incineration is dried on the shore in the open air, whence results a decomposition and a loss of salts from the spray of the sea, dew, rain, &c. The process of incineration itself is the main cause of the weakness of the product in iodine, as a certain quantity is volatilised, but it is chiefly to the siliceous sand mixed with the weed that the great loss is due. In fact, silica at high temperatures reacts upon the iodides, producing alkaline-earthy silicates, and eliminating a certain quantity of iodine. The author, therefore, proposes the following method:—The fresh weed is placed in baskets of iron-wire, moved by a turning crane, and steeped in a series of vats containing about 50 kilos. of good quicklime per cubic metre of water, and arranged in circular batteries. The weed passes in succession from vat to vat, and is exhausted of all its useful salts. The same series of successive immersions is pursued with fresh weed until the first vat marks 4·3° to 4·5° on the hydrometer (pèse-sels, probably a Baumé's glass, adapted for saline solutions). During this operation a double exchange takes place between the weed and the lime-water, by means of endosmosis. The time of steeping

RADIOMETERS.

THESE novel instruments have recently, as our columns testify, attracted considerable attention, not only amongst scientific amateurs but also amongst savants in different parts of the world. Since Mr. Crookes introduced the subject to the Royal Society, several communications have been submitted to that learned body, and to some of these and to certain outside critics the inventor of the instrument has now replied. At the meeting of the Royal Society, on March 23d, Dr. A. Shuster read a paper on the "Nature of the Force producing the Motion of a Body exposed to Rays of Heat and Light," of which the following is an abstract:

"Mr. Crookes has lately drawn attention to the mechanical action of a source of light on delicately suspended bodies *in vacuo*; I have made a few experiments with the view of finding out the seat of the reaction which evidently must tend to move either the inclosure or the source of light. I have found that the action and reaction is entirely between the light bodies suspended *in vacuo* and the exhausted vessel."

Mr. Crookes' "Light-Mill" was suspended by means of two cocoon fibres, forming a bifilar suspension from the top of a vessel which could be exhausted. A slight movement of the inclosure could be easily detected by means of a concave mirror attached to it. A beam of the oxyhydrogen lamp was concentrated on the light-mill, which then revolved 200 times a minute. The light was cut off at the beginning of the experiment by means of a screen, and the position of rest of the glass vessel was read off by means of the dot of light on the scale. The screen was then suddenly removed, and in every case a large deflection of the glass vessel was observed. The vessel was deflected in the opposite direction to that in which the mill turned. When the velocity of the mill had become constant, the vessel turned to its original position of rest, but on suddenly cutting off the light the vessel was again deflected, but in the opposite direction as on starting the experiment. The vessel, therefore, now turned in the same direction in which the mill turned.

These experiments are easily explained on the assumption that the force acting on the vessel inclosing the light-mill is exactly equal and opposite to that acting on the mill itself. While the velocity of the mill in one direction is increasing, a force acts in the opposite direction on the vessel. When the velocity has become constant, the force which tends to drive the mill round is exactly counterbalanced by the resistance which opposes the motion of the mill. The two forces acting on the vessel will therefore counterbalance, and the vessel will return to its original position of rest. When the light is cut off, the resistance will stop the motion of the mill. The reaction of the resistance will act on the inclosure, and the inclosure will turn in the same direction as the mill. By means of the reaction on the inclosure I have been able to calculate the strength of the force; and I have found that the pressure on a surface on which the light of equal intensity to that used in my experiments falls is equal to that produced by the weight of a film of water equal in thickness to the length of a wave of violet light.

At the last meeting of the Royal Society Mr. Crookes read a paper on the "Movement of the Glass Case of a Radiometer," in which he said: During the discussion which followed the reading of Professor Reynold's and Dr. Shuster's papers at the last meeting of the Royal Society, I mentioned an experiment bearing on the observations of Dr. Shuster. I have since tried this in a form, and as the results are very decided and appear calculated to throw light on many disputed points in the theory of these obscure actions, I venture to bring a description of the experiment, and to show the apparatus at work, before the society.

A large radiometer in a four-inch bulb was made with ten arms, eight of them being of brass, and the other two being a long watch-spring magnet. The discs were of pith, blackened on one side. The power of the earth on the magnet is too great to allow the arms to be set in rotation ... brought near, but once started it will continue to revolve with the light some distance off. This radiometer was floated in a vessel of water and four candles were placed round it, so as to set the arms in rotation. A mark was put on the glass envelope so as to enable a slight movement of rotation to be seen. The envelope turned very slowly a few degrees in one direction, then stopped and turned a few degrees the opposite way; finally it took up a uniform but excessively slow movement in the direction of the arms, but so slow that more than an hour would be occupied in one revolution.

A powerful magnet was now brought near the moving arms. They immediately stopped, and at the same time the glass envelope commenced to revolve in the opposite direction to that in which the arms had been revolving. The movement kept up as long as the candles were burning, and the speed was one revolution in two minutes. The magnet was removed, the arms obeyed the force of radiation from the candles, and revolved rapidly, whilst the glass envelope quickly came to rest and then rotated very slowly the same way as the arms went.

The candles were blown out; and as soon as the whole instrument had come to rest, a bar-magnet was moved alternately from one side to the other of the radiometer, so as to cause the vanes to rotate as if they had been under the influence of a candle. The glass envelope moved with some rapidity (about one revolution in three minutes) in the direction the arms were moving. On reversing the direction of movement of the arms the glass envelope changed direction also. These experiments show that the internal friction, either of the steel point on the glass socket, or the vanes against the residual air, or of both these causes combined, is considerable. Moving the vanes round by the exterior magnet carries the whole envelope round in opposition to the friction of the water against the glass.

As there is much discussion at present respecting the cause of these movements, and as some misunderstanding seems to prevail as to my own views on the theory of the repulsion resulting from radiation, I wish to take this opportunity of removing the impression that I hold opinions which are in antagonism to some strongly urged explanations of these actions. I have on five or six occasions specially stated that I wish to keep free from theories. During my four years' work on this subject I have accumulated a large fund of experimental observations, and these often enable me to see difficulties which could not be expected to occur to an investigator who has had but a limited experience with the working of one or two instruments.—*English Mechanic.*

18

A few days since, at the London Institution, Dr. Crookes read a paper on the radiation of light, in which he spoke of some practical applications that might be made of his discoveries. His scientific work is already well known, but these applications were for the first time laid before the public. He suggests that the torsion balance, which he has throughout used for testing the amount of action caused by the approach of light to it, should be employed as a test for the purity of our gas supply. First he would test the quality of the standard candles used, which it is known really vary very much when that variation is regarded from the standpoint of scientific accuracy. Then with the torsion balance, he would test the comparison between the gas and the standard candle, the slightest motion of the balance being capable of being recorded by the index scale on which the reflecting mirror shines. The other suggestion was the application of the rotating apparatus to meteorological purposes. He has arranged the windmill rotating wires with pith balls, so that they carry round a small magnet suspended beneath them. Their rate of rotation depends on the amount of light that falls on them.

Near the magnet attached to them is suspended another magnet, which oscillates as the attached magnet presents alternately its north and south poles. This oscillation is arranged to make and break an electric circuit, which, by a wire that may be of any length, is connected with a recording Morse machine worked by clockwork. Each revolution of the rotating pith balls is thus recorded by a punch of the Morse on a strip of continuous paper, and so a self-recording account of the amount of light falling at any place may be kept.

In our present meteorological records, Dr. Crookes observes, we notice heat, rain, and pressure of atmosphere; but light, the most important influence, both as regards health and agriculture, is neglected, because not till now have means of measuring it been known.

THE RADIOMETER OF MR. CROOKES.

IN a memoir read before the Academy of Padua by Prof. F. Rosetti, the author concludes his paper as follows: "After the exhibition which I have performed you will be convinced that the radiometer is not an instrument destined merely to attract general attention by reason of its novelty and the curious phenomena which it presents, but that it may serve as a prompt and sensitive thermoscope, and, if used with proper precautions, also as a photometer. It is a novel acquisition for science, both from a theoretical and a practical point of view, and as such it is capable of many applications." The author then describes a modification of the instrument for the purpose of registering the intensity of the solar radiations.

MOVEMENTS PRODUCED BY LIGHT AND HEAT, AND ON THE RADIOMETER OF MR. CROOKES.

By Dr. A. G. Barthi.

A LUMINOUS or thermic pencil which falls upon any body produces a movement due to four causes—(1) Action of the heated sides. (2) Currents of air produced around the heated body itself. (3) Reaction of gases or vapors liberated by heat. (4) Reaction of air heated by contact with the surface upon which the rays fall. On suppressing these causes in the best possible manner, incident light was no longer found to produce attraction or repulsion. These results, however, do not prove that a very feeble impulsive action is not exerted by heat or light.

Dec. '76

19

since been sent to keep company with Phlogiston and the four elements. It can be used, however, to explain the action of the radiometer with charming simplicity. If we hang a thin board from the end of a string so as to make a pendulum, it will suffice to throw a handful of shot at the board to set it in motion. Substitute for the board one of the discs of a radiometer, and for the shot, light corpuscules, projected, say, from a candle, and we have our explanation complete. It is known now, however, that light is not a fluid ponderable or imponderable, but is a mode of motion of that ether which pervades the universe, and that the sensation of colour is not due to the specific force of impact of corpuscules, but to the varying length of the light waves of vibration in the ether. We need not, we think, excuse ourselves for not giving here a more complete exposition of the undulatory theory of light. If our readers will realise the existence of a still pond of ether in which a luminous body sets up waves, as when a stone is thrown into a pool, they will have grasped all that it is for our present purpose necessary that they should comprehend. Let it be clearly understood that the true corpuscular theory supposes the motion of a molecule in a direct line, at a velocity of, in the case of white light, 190,000 miles in a second; but that, according to the undulatory theory, there is no direct movement of translation whatever, but that particles moving through a very small range transmit that motion to other particles with which they come in contact.

It will be seen that it is by no means an easy thing to supply a satisfactory explanation of the rotation of a radiometer on the undulatory theory. Mr. Crookes, in all cases, speaks of repulsion by radiation; that is to say, the heat or the light radiated by a hot or cold body *repels* the surface of the waves of the radiometer. This circumstance of repulsion must not be forgotten; it is really a very important phenomenon. Those who have had any experience in hydraulic works, know that waves which are not waves of translation exert no force of impact. A bottle will rise and fall quickly on an Atlantic swell without falling an inch to the right or left; if, then, light waves, as they are called, were strictly analogous to the ring waves found on a pond when a stone is thrown into it, the radiometer would remain at rest. It is rendered clear, however, not only by the action of the radiometer, but by other considerations, that a light wave is in only a limited sense identical with a water wave. A true wave cannot be created within the mass of a fluid; it is essentially a phenomenon proper to extended surface; but in the ether we have a something which is without surface, inasmuch as it pervades all space, and we are driven to the conclusion that the force operating on the blackened pith of the radiometer is that which would have been communicated to succeeding portions of ether had not the pith surface intervened, and that, in a word, we are supplied with direct evidence of the united force of vibration of the molecules at the extremity of a column of ether, the section of which is equal in area to that of a radiometer vane. Mr. Crookes, in some sense accepting this view, has actually weighed a beam of light, and finds that the sun, when unclouded, exerts a repulsive force on the surface of the earth of 57 tons per square mile, or on the whole semi-surface of the earth of three thousand millions of tons. And here we come upon a direct and very beautiful analogy between the action of light considered as a mode of motion in the ether, and the phenomena of dilation, or more strictly speaking, of pressure, in a gas. To use Tyndall's illustration, air distends a bladder, because the molecules of the gas continually hammer on the inside the walls of the bladder limiting the range of vibration of those molecules next to them. In the same way the vibrating molecules of the ether hammer at the disc of a radiometer and cause its repulsion. So far the theory is rational; and we find that the rotation of the disc of a radiometer is consistent with the undulatory theory. But it will be found, we think, on examination, that the satisfactory character of this hypothesis is more apparent than real. If we are to derive motion from that of molecules of ether in vibration, then it is clear that the more impenetrable the surface is to these molecules, the greater will be the effect produced on that surface. But the fact is, that although a metallic surface brightly polished is just that which we may conceive as being best adapted to receive an impulse from a vibrating ether molecule, yet it is found that a black or absorbent surface into which the light wave sinks as a hammer would into putty, is really that which is most forcibly repelled in the case of the radiometer. This objection has already been urged against the vibratory impulsive theory; and different attempts have been made to explain the objection away. To the consideration of these we may return another time. There is, however, a most important phenomenon connected with the radiometer which up to the present moment has, so far as we are aware, received no attention whatever, and which must meet with some explanation before it is worth while to go into more or less abstract questions connected with the varying influence of different surfaces on the performance of the apparatus.

The phenomenon to which we allude was first exhibited by Mr. Crookes at a *soirée* given at Burlington House on the 5th inst. One of the instruments exhibited we shall describe in Mr. Crookes' own words:—"Radiometer showing rotation of the glass envelope when the vanes are held fixed in space. The radiometer carries a magnet on its arms, and is floated on water so as to be free to move. The vanes are held stationary by an outside magnet. *On allowing radiation to fall on the black surfaces of the vanes the glass envelope rotates.*" The italics are ours. Let us see what they imply. Mr. Crookes has apparently failed himself to see anything specially noteworthy in the circumstance as stated, that if the arms are held the glass globe revolves, and yet it is not too much to say that this is really an exceedingly startling fact which may go far to upset the whole theory of the radiometer. At the first glance, many of our readers will no doubt be disposed to regard the rotation of the glass as an instance of what we may term reciprocity of force. Thus, we know that if the paddle-wheels of a steamer were held at rest and the engines were sufficiently powerful, the whole ship would be caused to rotate round the shaft. A screw steamer would rotate in a different plane, from the same cause. In the case of the Cigar Ship, a vessel with extremely small initial stability, a balance weight consisting of about 15 tons of lead had to be shifted when the engines were started to counteract their tendency to rotate the ship in one direction while the screws revolved in the other. Now, if we regard Mr. Crookes' radiometer wheel as analogous to a ship's paddles, and the glass envelope as corresponding to the hull, there is nothing at first sight anomalous in the rotation of the glass envelope. It will be seen in a moment, however, that there is no analogy whatever between the ship and the radiometer. In the first case the motion of the paddle-wheels is derived from within, and the ship is the fulcrum. If the engines were fitted up outside the ship, their action would set up no rotating force on the hull. Now, in the case of the radiometer, it is obvious that according to received ideas no fulcrum is required to cause its rotation except that supplied by the body giving out the light. Let us suppose this to be a candle, then as action and reaction are always equal and opposite, it follows that the force repelling a radiometer disc in one direction is equally exerted in repelling the candle flame in an opposite one; the glass globe, being transparent, can take no part in the matter whatever. But if we find that, instead of this being the case, it is practically a matter of indifference whether the globe being held fast the radiometer revolves, or the radiometer wheel being held fast the globe revolves, it is impossible to escape one of two conclusions; either the presence of an envelope is essential to the rotation of the radiometer wheel—apart altogether from the circumstance that without it we could have no vacuum—or that the light reflected from the radiometer vanes exercises some peculiar influence on the glass of the envelope. To name only one of several perplexing things connected with the phenomena of rotation of the glass, we have the fact that although Mr. Crookes finds it desirable or even necessary to blacken his pith surfaces, the glass requires no blackening to insure its rotation. For the moment we shall leave the subject here. It is one well worth further investigation, and it is to be hoped that some satisfactory solution of the problem of the rotation of the glass envelope will be supplied. It is the most bewildering phenomenon that has recently been remarked in the world of physical science.

THE EXHIBITION OF SCIENTIFIC APPARATUS.

PHYSICS (HEAT).

As regards this branch of the section of physics the Exhibition is peculiarly interesting, as it contains a comparatively large number of instruments used by distinguished physicists in determining data of high theoretical importance.

Our attention is first attracted by a large ungainly-looking and quasi-cylindrical vessel. It is the ice-calorimeter constructed and used by Lavoisier and Laplace. The diameter at the top is just a foot and a half. Lifting the lid, we see the compartment in which was placed the body, the specific heat of which it was required to determine. The walls of this chamber were formed by numerous interlacing wires, the interspaces of which facilitated the radiation of heat from the body to the surrounding ice. The diameter of this chamber is 9 in., its length 1 ft. Concentric with this compartment are two others, each of which has at its under-surface a stop-cock to afford free exit to the water of fusion. Knowing the temperature of the body at the beginning and at the end of the operation as well as the weight of the water obtained from the fusion of the ice, we have sufficient data to calculate the specific heat of the body in question. The length of the third and outermost compartment as measured from the stop-cock to the lid is 2 ft. 2 in.; the whole apparatus is supported on a tripod stand, the upper surface being just 3 ft. from the ground. Although the results obtained from this calorimeter are wanting in accuracy, still the apparatus is invested with the twofold interest that must invariably attach to the earliest instruments used in any special subject of research, as well as to its having been devised and used by such eminent men of science as Lavoisier and Laplace.

At a few paces from this calorimeter is a model of the apparatus used by Dulong in his studies on the same subject of specific heat. The method adopted by this savant is known as the "method of cooling," and depends upon the principle that bodies of different specific heats will take different times to cool through the same number of degrees. Close beside the model, which was sent from the École Polytechnique, is the identical cylindrical vessel used by Dulong, and contiguous with this cell is a very small "worm" or serpentine of gold used by Dulong in his researches upon the specific heat of gases.

over

(1)

contained. The weight of the water being exactly determined, and its increase of temperature observed, it was shown that every pound-degree Fahrenheit was equivalent in energy to 772 foot-pounds. The same experiment was repeated, a slight modification being introduced by substituting mercury for water, the equivalent thus found was 775.* This second apparatus may also be seen in the same case as the first. To many this must be among the most interesting objects in the Loan Exhibition.

The subject of radiant heat is well represented by a complete set of instruments contributed by M. Ruhmkorff, of Paris. The instruments are similar to those used by Melloni in his laborious and delicate investigations, and by Tyndall in his verification of the results obtained by the Italian philosopher. Together with these is placed the apparatus used by our distinguished professor in his researches on the absorption of radiant heat by gases and vapour. This latter consists of a brass tube 2½ in. in diameter and 4 ft. long. The two ends are closed by plates of a very diathermanous substance, viz., rock-salt. By means of two lateral tubulures, the tube may be exhausted and subsequently filled with any gas whose absorptive power it is desired to determine. The exhausted tube is placed in a horizontal position, heat from a Leslie's cube is allowed to fall upon one plate of rock-salt; it radiates through the whole length of the tube, emerges through the other diathermatous plate, and is received upon the surface of a delicate thermo-pile which is connected with a very carefully calibrated galvanometer. In the mean time, rays from a second source of heat, a compensating cube, are concentrated upon the other side of the pile, and the distance is so arranged that the needle of the galvanometer stands at zero when there is a vacuum in the tube. If the tube be now filled successively with atmospheric air, with carbonic acid, and with ammonia, the needle will be but very slightly affected in the first case, but will undergo a considerable deflection with the carbonic acid, which will be further increased with the ammonia. Taking the quantity of heat absorbed by air as unity, the carbonic acid will be found to absorb 90 and the ammonia 1135 such units. Repeated experiments have shown that air, hydrogen, oxygen, and nitrogen differ but very little from a vacuum in their absorbing power. The whole of this important matter has been thoroughly investigated by Professor Tyndall, and it is not without singular pleasure that we gaze upon the very instruments used by him in that elaborate series of experiments.

In connexion with the above subject, we may add that there are some very fine specimens of rock-salt exhibited by W. Steeg, of Homberg, viz., a prism of this material 50×60 mm., a lens 75 mm. in thickness and 300 mm. in radius, and a plate measuring 60×60 mm.

In the same case in which these apparatus are disposed, viz., that of radiant heat, we find a number of those tiny instruments, equally remarkable for their ingenuity, and the hot warfare to which they have recently given rise. We mean the radiometers of Professor Crookes. It is plain that the organiser of this section was ready to do battle in favour of the theory which regards heat and not light as the *primum mobile* of this admirable scientific toy, which may yet forsooth revolutionise some of our cherished and well-framed theories.

There is a goodly collection of pyrometers. The most interesting, from an historical point of view, are those made by Wedgwood, Daniell, and the many-sided Muschenbroek. They are all small, but involve principles of considerable theoretical and practical value. These instruments are, however, superseded by the electrical pyrometer of Dr. Siemens, an invaluable instrument, which will be referred to later on.

Professor Tait, of Edinburgh, has contributed several apparatus relating to conductivity, viz., a bar of German silver about 9 ft. long, and 1¼ in. thick, with nine thermometers inserted at different points of the length; a second of the same dimensions but of iron, and a third of copper about 4 ft. long, and carrying fourteen thermometers. These bars are intended for repeating Despretz's celebrated experiments, by which he showed that if the distances of the thermometers from the source of heat be in arithmetical progression, the excess of the recorded temperatures over that of the surrounding air will decrease in geometrical progression. We may observe that the homogeneousness of the bar is altered by the insertion of the thermometer bulbs, and hence a

* The value now generally accepted in this country is 772.

source of error is introduced which detracts from the value of the data obtained by such experiments. The same subject was investigated by Wiedemann and Franz by applying a very small thermo-pile to different parts of the bar. The numbers obtained differ considerably from those given by Despretz. There is yet another appliance based upon the principle of conduction, which few will fail to recognise as Sir Humphrey Davy's safety-lamp. Its very look is a fair guarantee of its originality; all doubt, however, is removed by the manuscript label, which states that it has been sent from the collection of the Royal Society. The wire gauze is extremely fine. This precious model was made by Sir Humphrey and presented to the Royal Society, together with his memorable paper upon the same subject, on the 11th of January, 1816.

Thermometry is very well represented; there is no lack of maxima, minima, wet and dry bulb, differential, and other thermometers. There is also a good collection of manometers with drawings, &c. But by far the most curious measurer of temperature is the thermometer of Galileo, which is exhibited together with the other instruments of this illustrious philosopher. Until recently the physician Sagredo was considered the inventor of the thermometer; but there is now strong positive evidence that Galileo's was made some time before the year 1597. It is an air thermometer, consisting of a bulb and a tube dipping into a small cistern of water. It was originally intended for medical purposes. It is still in excellent order, and high authority has stated that its delicacy is such as not easily to be surpassed.

We find another thermometer in this most valuable collection, which is also an early specimen, having been made in the seventeenth century. It originally belonged to the Florentine Accademia del Cimento, but now belongs to the Royal Institution, having been presented by Sir Henry Holland. There is also another thermometer which deserves attention from the novel feature of its graduation. It is called the Milligrade thermometer, from the fact that the interval between the freezing and the boiling point of mercury is divided into 1000 parts. The interchange of readings between this and Centigrade scale will be obvious from the consideration that mercury freezes at —40 deg. C., and boils at 360 deg. C.; hence 400 deg. C. must equal 1000 M., or 1 deg. C. = 2½ deg. M. According to this scale water boils at 350 deg., and freezes at 100 deg., the interval (250 deg.) being just one-fourth that between the freezing and boiling points of mercury. The practical advantage of such a graduation seems to be: first, the avoidance of the minus sign, all readings under 100 M. indicating temperatures below zero; and, secondly, the avoidance of fractions (owing to the smallness of the degrees) which are often necessary to express the boiling point under certain resistances. The exhibitor of this novel instrument is John Williams, F.C.S.

This section, as will now appear, is replete with interest, and will amply repay several visits.

April 27/76

Floating Radiometers

In Mr. Crookes' paper reported in NATURE, vol. xiii. p. 489, occur the following words: "The envelope turned very slowly a few degrees in one direction, then stopped and turned a few degrees the opposite way." Assuming that this is rightly reported, it is inexplicable to me how Mr. Crookes could have written it. For, as the lawyers say, it is "void from ambiguity." The whole question between Mr. Crookes and Dr. Schuster appears to me to turn on the one point ignored by the former. When the rotation of the envelope began, in which direction was the first oscillation? To say that the envelope first turned in one direction and then in the other is simply to say that it oscillated, which, while it is a shorter mode of expressing the same thing, is an equally useless expression. The very nerve of the problem lies in the point omitted. If the first oscillation of the envelope was in the direction opposite to that of the mill, it is surely incontestable that the kick, which caused it, could not be the effect of any external force acting on the discs only.

Valentines, Ilford C. M. INGLEBY

RADIOMETERS[1]

DURING the discussion which followed the reading of Prof. Reynolds's and Dr. Schuster's papers at the last meeting of the Royal Society I mentioned an experiment bearing on the observations of Dr. Schuster. I have since tried this in a form; and as the results are very decided and appear calculated to throw light on many disputed points in the theory of these obscure actions, I venture to bring a description of the experiment, and to show the apparatus at work, before the Society.

I made use of a radiometer described in a paper communicated to the Society in January last. I quote the description from paragraph 184. "A large radiometer in a 4-inch bulb was made with ten arms, eight of them being of brass and the other two being a long watch-spring magnet. The discs were of pith, blackened on one side. The power of the earth on the magnet is too great to allow the arms to be set in rotation unless a candle is brought near, but once started it will continue to revolve with the light some distance off."

Nature April 20/76

This radiometer was floated in a vessel of water and four candles were placed round it, so as to set the arms in rotation. A mark was put on the glass envelope so as to enable a slight movement of rotation to be seen. The envelope turned very slowly a few degrees in one direction, then stopped and turned a few degrees the opposite way; finally it took up a uniform but excessively slow movement in the direction of the arms, but so slow that more than an hour would be occupied in one revolution.

A powerful magnet was now brought near the moving arms. They immediately stopped, and at the same time the glass envelope commenced to revolve in the opposite direction to that in which the arms had been revolving. The movement kept up as long as the candles were burning, and the speed was one revolution in two minutes.

The magnet was removed, the arms obeyed the force of radiation from the candles, and revolved rapidly, whilst the glass envelope quickly came to rest and then rotated very slowly the same way as the arms went.

The candles were blown out; and as soon as the whole instrument had come to rest, a bar-magnet was moved alternately from one side to the other of the radiometer, so as to cause the vanes to rotate as if they had been under the influence of a candle. The glass envelope moved with some rapidity (about one revolution in three minutes) in the direction the arms were moving. On reversing the direction of movement of the arms the glass envelope changed direction also.

These experiments show that the internal friction, either of the steel point on the glass socket, of the vanes against the residual air, or of both these causes combined, is considerable. Moving the vanes round by the exterior magnet carries the whole envelope round in opposition to the friction of the water against the glass.

As there is much discussion at present respecting the cause of these movements, and as some misunderstanding seems to prevail as to my own views on the theory of the repulsion resulting from radiation, I wish to take this opportunity of removing the impression that I hold opinions which are in antagonism to some strongly urged explanations of these actions. I have on five or six occasions specially stated that I wish to keep free from theories. During my four years' work on this subject I have accumulated a large fund of experimental observations, and these often enable me to see difficulties which could not be expected to occur to an investigator who has had but a limited experience with the working of one or two instruments.

PROCEEDINGS OF SOCIETIES.

PHYSICAL SOCIETY.

December 16th, 1876.

Professor G. C. FOSTER, F.R.S., President, in the Chair.

THE following candidate was elected a Member of the Society:—Mr. W. Baily, M.A.

Mr. CROOKES described some of the most recent results he has obtained in his experiments on the radiometer, and exhibited many beautiful forms of the apparatus, most of which have been devised with a view to decide on the correct theory of the instrument. He commenced by describing the arrangement he has used for some time past in studying the resistance offered by air and other gases to the rotation of a mica disc. It consists of a mica plate suspended by a fibre of glass, and enclosed in a chamber which can be exhausted to any required extent. A mirror is attached to the mica, and the movement of a luminous point reflected from it shows that the decreasing swings form a logarithmic curve, and Mr. Crookes takes the logarithms of the decrements of the swings as a measure of the viscosity of the gas under examination. From the normal atmospheric pressure to the best vacuum which can be obtained by the ordinary air-pump this decrement remains nearly constant, and these experiments have been carried on in vacua of remarkable perfectness, the highest exhaustion obtained being represented by 1 millimetre on a scale of 10 miles, a point which was attained by means of a Sprengel pump with improvements by Mr. Gimingham, and measured by a McLeod gauge. If the "logarithmic decrement" be represented by 325 at a pressure of 760 m.m., it is not reduced to 70 until the pressure has been reduced to 35-millionths of an atmosphere, and at this point the action of light on a radiometer is at a maximum. On continuing the exhaustion this influence is found to decrease, and Mr. Crookes concludes that in a perfect vacuum the log dec. would not be zero, but about 0·01; that is, a mica plate would not continue to oscillate for ever, a fact probably due to the viscosity of the glass fibre. About fifteen different forms of the radiometer were exhibited, and their inventor has satisfied himself that the theory of their action proposed by Mr. G. Johnstone Stoney is the only one capable of completely accounting for their action, and he considers it to be in all probability the correct one. By means of a double radiometer, consisting of two globes of different diameters, and having a wide opening between them, and provided with a four-armed fly which can be made to rotate in either bulb, it has been shown that, other things being equal, the velocity of rotation decreases as we increase the diameter of the bulb. As, on the molecular-movement theory, the rotation is due to a throwing off of particles from the blackened surface of the mica, it follows that, if a piece of transparent mica be attached to each fly in front of the blackened surface, the rotation will take place in the opposite direction, and this proved on experiment to be the case. And, further, when such a plate is placed on either side of the vanes, the motion of the instrument is almost entirely stopped. As these facts can be explained on the "molecular movement" or the "evaporation and condensation" theory, Mr. Crookes arranged a radiometer having four transparent mica vanes, and mounted in a rather large bulb. At the side of the bulb a plate of mica, blackened on one side, is so fixed in a vertical plane that the vanes can pass, and when light shines on this fixed plate the fly is found to rotate, a fact which in itself disproves the latter theory. Many other curious forms were exhibited, in some of which the vanes were cup-shaped, as Mr. Crookes has found these to act as well as the ordinary form, a convex surface acting as though it were blackened. In conclusion, he exhibited a photometric four-vaned radiometer, in which the fly was attached to a small magnetic needle, and this might be so checked by an external magnet that the strongest light would be incapable of causing the needle and vanes to make a half rotation. If the circumference of the globe be graduated, and the apparatus be brought within the influence of a source of light, the angle to which the needle is deflected will be a direct measure of the intensity of the light, and Mr. Crookes showed that by a simple arrangement such an instrument might be rendered self-recording.

Prof. DEWAR exhibited a simple electrometer which he has designed, founded on the discovery of Lippman that the capillary constant is not really independent of the temperature or the condition of the surface, but is a function of the electromotive force. If a capillary tube be immersed in mercury, and dilute sulphuric acid be placed in the tube above the mercury, and a current from a Daniel's cell be so passed through the liquids that the mercury forms the negative pole, the column will be depressed to an extent dependent on the diameter of the tube. In making an electrometer, Prof. Dewar has increased the sensitiveness by connecting two vessels of mercury by means of a horizontal glass tube filled with the metal, except that it contains a bubble of dilute acid. The tube must have an internal diameter of 2 millimetres, and it is essential that it be perfectly clean, uniform in diameter, and horizontal. The instruments exhibited were constructed by Messrs. Tisley and Spiller, and Prof. Dewar showed that it is possible by means of them to measure an electromotive force equal to 1-10,000th of a Daniel's cell; forces capable of decomposing water must be measured by causing two currents to act against each other. The index bubble is brought to zero by uniting the mercury cups by a wire. The apparatus is very convenient, as it requires no preparation, and is extremely simple in its action. He then showed an instrument arranged by Mr. Tisley for producing a current by the dropping of mercury from a small orifice into dilute sulphuric acid. If the vessels containing the mercury and the sulphuric acid be connected by a wire a current is found to traverse it, and Prof. Dewar explained how the electrolysis of water might be effected by this means. He then exhibited a delicate manometer suitable for measuring very slight variations of pressure, and he illustrated the use of it for proving Laplace's law that the internal pressure, multiplied by the diameter of a soap-bubble, is constant. It consists of a U-tube, one arm of which is about 35 inches long, and is bent horizontally, and levelled with great care. If the shorter arm be connected with a tube on which a bubble has been blown, and the diameter of the bubble be varied, the position of the extremity of the alcohol column will be found to vary in accordance with the above law.

23

up with sandstones, conglomerates, and breccias. The red stain of these deposits, occasional pseudomorphs of rock-salt and layers of gypsum, combined with ripple-marks and sun-cracks seem, as Prof. Ramsay has suggested, to indicate the concentration of the saline waters which filled these basins; while further evidence of the unwholesome nature of the water may be indicated by the general paucity of fossils in the strata, and by the immense numbers of well-preserved fishes which are sometimes met with crowded into a small space, as if they had come from fresher water elsewhere, and had been inclosed and killed in scattered pools. The peculiar breccias and brecciated conglomerates of the Upper Old Red Sandstone have been compared to some recent Glacial deposits, and the resemblance has been pointed out between the form of the stones in these deposits, and those in common boulder-clay. It should be noted also that in many cases these breccias occur in old valleys, and bear many of the characters of valley-moraines. Such are those to the east of Ullswater, and those which flank, and in some places penetrate the Lammermuir Hills. In the latter district worn dome-shaped bosses of rock underlying the breccias recall the aspect of true *roches moutonnées*. Another glacial feature is suggested by the basin-shaped hollows (apparently sometimes true rock-basins) in which the deposits lie. Further indications of ice are given by the remarkable patches of angular and rounded stones scattered through the red sandstones of Arran, the occurrence and position of which may be accounted for on the supposition that they are portions of shore-gravel, which have been frozen and transported in cakes of floating-ice.

Indications of terrestrial disturbance during the accumulation of the Upper Old Red Sandstone in Scotland are furnished by the Lammermuir Hills. Towards the close of the period, and thence through the deposition of the Lower Carboniferous rocks, volcanic action which seems to have been quiescent for a long interval, broke out again over the south of Scotland. To this period belongs the chain of old lavas and tuffs which may be traced from the mouth of the Nith eastwards by Langholm and the Tarras Water, to the head of the Slitrig Valley, and through the plain of the Tweed as far northwards as the Whiteadder. The Garlton Hills, Campsie Fells, and the ranges of hills which run down Renfrewshire and the north-east of Ayrshire, and are prolonged into Bute, the Cumbrays and Arran mark a prolonged series of volcanic eruptions during this same period. Probably the terraced hills of Lorne are of similar age. Traces of contemporaneous volcanic action occur likewise in the Upper Old Red Sandstone of the north of Scotland, and form a remarkable feature in the cliffs of Hoy, one of the Orkney Islands.

The author brought forward evidence to show that while the Upper Old Red Sandstone was being deposited in the British area, there existed outside that area a sea in which some of the characteristic corals, brachiopods, and other organisms of the time of the Carboniferous Limestone already existed. He pointed out the intercalation of limestone bands in the Red Sandstone series in Arran and elsewhere, a long way below the base of the Cement-stone group which underlies the Carboniferous Limestone. These calcareous bands, full of species of fossils which are familiar in the Carboniferous Limestone, seem to indicate that while, on the whole, the Upper Old Red Sandstone, and the red strata at the base of the Carboniferous system were deposited under conditions unfavourable to the presence of at least corals, crinoids, and molluscs, their formation was interrupted by intervals during which clearer and less saline water prevailed, perhaps owing to the removal of barriers which allowed the access of the main ocean with its animal forms into the closed lagoons and inland seas of the Upper Old Red Sandstone.

ON REPULSION RESULTING FROM RADIATION[1]

THIS paper contains an account of experiments on the action of radiation on bodies the surfaces of which have their radiating and absorbing powers modified by various coatings. The difference between a white and a lamp-blacked surface in this respect was at first not very decided, and experiments have been instituted with the object of clearing up some anomalies in the actions observed. Two pith discs, one white and the other black, are suspended on a light arm in a glass bulb by means of a fine silk fibre; after perfect exhaustion the white and black discs are found to be equally repelled by heat of low intensity, such as from the fingers, warm water, &c. A copper ball is then tried at gradually increasing temperatures. Up to 250° C. it repels both equally, above that the black is more repelled than the white, and at a full red heat the repulsion of the black disc is very energetic. A lighted candle acts with more energy than the red-hot copper.

The presence of even a small quantity of aqueous vapour in the exhausted apparatus almost, if not quite, neutralises the more energetic action which luminous rays appear to exert on a blackened surface.

After describing several different modifications and some new forms of apparatus devised to facilitate experiment, the author gives a drawing of an instrument which enables him to get quantitative measurements of the amount of incident light falling on it. It consists of a flat bar of pith, half black and half white, suspended horizontally in a bulb by means of a long silk fibre. A small magnet and reflecting mirror are fastened to the pith, and a controlling magnet is fastened outside so that it can slide up and down the tube, and thus increase or diminish sensitiveness. The whole is completely exhausted and then inclosed in a box lined with black velvet, with apertures for the rays of light to pass in and out. A ray of light reflected from the mirror to a graduated scale, shows the movements of the pith bar. The degrees of deflection produced by the light of a candle at distances from 6 feet to 35 feet are given.

The experimental observations and the numbers which are required by the theoretical diminution of light with the square of the distance, are sufficiently close, as the following figures show:—

Candle	6	feet off gives a deflection of		218°
"	12	"		
"	18	"	"	54
"	24	"	"	24·5
"	10	"	"	13
"	20	"	"	77
"	30	"	"	19
		"	"	8·5

The effect of two candles side by side is practically double, and of three candles three times that of one candle.

The action of various solid and liquid screens is next given.

A candle three feet off, giving a deflection of 180°, has its action reduced to the following amounts by

Yellow glass	... ...	161°
Blue "	... ...	102
Green "	... ...	101
Red "	... ...	128
Water "	... ...	47
Alum "	... ...	27

A candle on each side of the apparatus, and equidistant from it, keeps the index ray of light at zero; by shading off either one or the other the light flies off to either extremity of the scale. This gives a ready means of balancing two sources of light one against the other. Thus, &c.

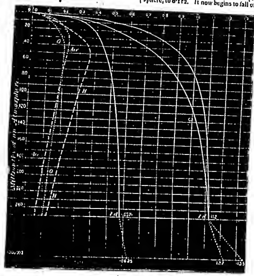
EXPERIMENTAL CONTRIBUTIONS TO THE THEORY OF THE RADIOMETER.*

PRELIMINARY NOTICE.

By WILLIAM CROOKES, F.R.S., &c.

INSTEAD of bringing another preliminary notice before the Society, I should have preferred reserving the announcement of my new results on the Repulsion resulting from Radiation until they were fit to be offered in a more complete form; but the radiometer is now so much occupying the attention of scientific men, and results of experiments with this and allied instruments are appearing so frequently in the scientific journals at home and abroad, that were I not to adopt this method of bringing the results of my more recent experiments before men of science, I might find myself anticipated in some or all of the conclusions at which I have arrived.



On June 15th last I mentioned to the Society that the repulsion resulting from radiation increases up to a certain point as I exhaust the air from the torsion apparatus. After long-continued exhaustion the force of radiation approaches a maximum, and then begins to fall off. I have since succeeded in experimenting at still higher exhaustions, and with different gases in the apparatus; and by means of a McLeod gauge attached to the mercury pump I have been able to measure the atmospheric pressure at any desired stage of exhaustion. I have not only measured the force of repulsion, but also the viscosity of the residual gas, and from the results plotted I have the observations in curves which accompany this paper, and which show how the viscosity of the residual gas is related to the force of repulsion exerted by radiation. These curves must not, however, be considered as representing more than the broad facts, for I have not included in them my final observations, which in all probability will introduce modifications in them.

In plotting these curves I have supposed my scale to be 1000 metres long, and to represent one atmosphere. Half-way up the scale therefore, or 500 metres, represents half an atmosphere; 999 metres up the scale represents an exhaustion of 1-1000th of an atmosphere; each millimetre, therefore, stands for the millionth of an atmosphere.

My results have principally been obtained at the top of the scale, and it is the last quarter of a metre which supplies the diagrams accompanying this paper.

When the residual gas is air, the viscosity (measured by the logarithmic decrement of the arc of oscillation) is practically constant up to an exhaustion of 250 millionths of an atmosphere, or 0·19 millim. of mercury, having only diminished from 0·126 at the normal pressure of the atmosphere, to 0·112. It now begins to fall off; at 200 millionths it is 0·110; at 100 millionths it is 0·096; at 50 millionths it is 0·078; at 20 millionths it is 0·052; at 10 millionths it is 0·035; and at 0·1 of a millionth of an atmosphere, the log. dec. has fallen to about 0·01. Simultaneously with this decrease in the viscosity, the force of repulsion exerted on a black surface by a standard light varies. It increases very slowly till the exhaustion has risen to about 70 millionths of an atmosphere; at about 40 millionths the force is at its maximum; and it then sinks very rapidly, till at 0·1 millionth of an atmosphere it is less than one-tenth of

ON REPULSION RESULTING FROM RADIATION.—PART II.*

By WILLIAM CROOKES, F.R.S., &c.

(Continued from p. 220).

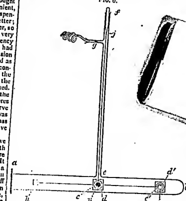
101. The difficulty which attended experiments with the balances and bulb apparatus used at first was to bring the moving part accurately back to zero, and also to measure the deflection produced. I therefore tried several plans of giving a fixed zero-direction to the movable index. Thus a piece of magnetic oxide of iron was cemented to one end of the index, and a permanent magnet was brought near it. This answered pretty well, but was inconvenient, besides not being sufficiently accurate. A bifilar suspension from cocoon-fibres seemed likely to succeed better; but the difficulty of suspending the rod in this manner, so as to get exactly the same tension on each fibre, was very great, and unless this was done there was more tendency to move in one direction than in the other. When I had succeeded in suspending the needle with an equal tension on each silk fibre, I found their elasticity to vary; and as soon as the vacuum was approached one was sure to contract more than the other, twisting the needle out of the axis of the tube, and sometimes causing it to touch the side. This method of suspension was therefore abandoned.

By increasing the length of the needle, and also of the fibre used to suspend it, it was possible to employ fibres with a considerable amount of torsion, and still preserve the delicacy of the apparatus. Fine platinum wire was first tried; but this was soon abandoned in favour of glass fibres, which were found to answer so perfectly that I have since used nothing else.

102. Fig. 7 shows the form of apparatus which I have finally adopted, as combining the greatest delicacy with facility of obtaining accurate observations, and therefore of getting quantitative as well as qualitative results. It is a torsion apparatus in which the beam moves in a horizontal plane, and may be called a horizontal torsion balance. *a b* is a piece of thin glass tubing, sealed off at the end *b* and ground perfectly flat at the end *a*. In the centre a circular hole, *c*, is blown, and another one, *c'*, at the end; the edges of these holes are ground quite flat. *a*, *c*, and *c'* can therefore be sealed up by cementing flat transparent pieces of plate glass, quartz, or rock-salt, *a*, *d*, and *d'* on to them (83). To the centre of *a b* an upright tube, *e f*, is sealed, having an arm, *g*, blown on to it for the purpose of attaching the apparatus to the pump. *h i* is a glass index, drawn from circular or square (22) glass tube, and as light as possible consistent with the needful strength. A long piece of this tube is first drawn out before the blowpipe; and it is then calibrated with mercury until a piece is found having the same bore throughout; the necessary length is then cut from this portion. *j k* is a very fine glass fibre, cemented at *j* to a piece of glass rod, and terminating at *k* with a stirrup, cut from aluminium foil, in which the glass index, *h i*, rests. In front of the stirrup is a thin glass mirror, shown at *k*, silvered by Liebig's process, and either plane or concave as most convenient. At the ends of the glass index (*h i*) may be cemented any substance with which it is desired to experiment; for general observations I prefer to have these extremities of pith, as thin as possible, and exposing a surface of 10 millimetres square. The pith may be coated with lampblack or silver, or may retain its natural surface.

103. The preparation of the suspending thread of glass requires some care. It should be drawn from flint glass, as this gives much tougher threads than foreign glass. The diameter varies with the amount of torsion required; it may be 0·001 inch or less. I select the piece best adapted for the special experiment in the following way:—Several threads of glass are first drawn out before the blowpipe, and a certain number selected as being likely to answer the purpose. These are then suspended side by side to a horizontal rod and equalised as to length. A piece of glass rod, about 2 inches long, which is always kept for this purpose, is then cemented by shellac on to the end of one of the threads. Air currents are then cut off by a glass screen, and the thread being set in movement by a slight twist, the torsion is measured by timing the oscillations. This having been done with each thread in succession, one is selected and mounted in the apparatus. If it works properly, well and good; if not, it is easy to select a thread having the requisite amount of torsion, more or less, and substitute it for the one first used.

Fig. 6.



In fitting up one of these apparatus threads were drawn out which were found to require, respectively:—

44 seconds,
30 ,,
28 ,,
11 ,,
and 3½ ,,

for a half oscillation when the glass weight was hung on to their ends. The one oscillating in 30 seconds was first used, but was found to give insufficient torsion. The one making half an oscillation in 11 seconds was then used, and was found to answer well. Before I adopted this plan days were frequently wasted in the attempt to hit upon a glass thread of the requisite degree of fineness.

104. In taking accurate observations with an apparatus of this description, it is necessary to support it on a stand firmly fastened to a main wall. When resting on a bench, or connected in any other way to the floor, there is a constant oscillation which keeps the index from zero.

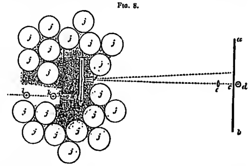
The apparatus being fastened firmly to its stand, accurately levelled, and sealed on to the pump, a divided scale, *a b* (fig. 8), is placed four feet from the small mirror; and immediately beneath the scale is a narrow brass slit,

c, illuminated by a lamp, *d*. In front is a lens, *e*, which throws the image of the slit on to the mirror, where it is reflected back again on to the divided scale. Here the angular movement of the bright line of light shows the

for some weeks, as the residual moisture in the pith will then have been absorbed by the sulphuric acid in the pump.

(To be continued.)

Fig. 8.



minutest attractive or repulsive force acting on the pith at the extremity of the movable index.

In order to keep the luminous index accurately at zero, except when experiments are being tried, extreme precautions must be taken to keep all extraneous radiation from acting on the apparatus. A slightly conical paper tube, *f*, about 6 inches long, and as narrow as the angular movement of the ray of light will admit of, is cemented on to the glass window in front of the mirror; and a similar tube, *g*, is cemented on to the quartz window in front of the pith surface on which radiation is to act. The latter tube is furnished with card shutters, *h*, *i*, at each end, capable of easy movement up and down. The whole apparatus is then closely packed on all sides with a layer of cotton-wool, about 6 inches thick, and outside this is arranged a double row of Winchester quart bottles, *j*, *j*, filled with water and covered with brown paper, spaces being only left in front of the paper tubes. *k* and *l* represent the positions of the candle 140 and 280 millims. distant from the pith. The whole arrangement has the appearance shown in fig. 8.

105. I will not discuss at present the phenomena presented when the apparatus is full of air, or when the vacuum is imperfect, but will proceed to the effects observed when the exhaustion has been pushed to the highest obtainable degree. However much the results may vary when the vacuum is imperfect, or when the apparatus is full of air, I always find them agree amongst themselves when the residual gas is reduced to the minimum possible; and I have also ascertained that it is of no consequence what this residual gas is. Thus I have started with the apparatus filled with various vapours and gases, such as air, carbonic acid, water, iodine, hydrogen, or ammonia; and at the highest rarefaction I find no difference in the results which can be traced to the residual vapour, assuming any to be present. A hydrogen vacuum seems neither more nor less favourable to the phenomena than does a water or an iodine vacuum. If moisture be present to begin with, it is necessary to allow the vapour to be absorbed by the sulphuric acid of the pump, and to continue the exhaustion with repeated warming of the apparatus until the aqueous vapour is removed; then only do I get the best results. When pith surfaces are used at the extremities of the glass beam, they should be perfectly dry; and they are more sensitive if the apparatus has held a vacuum

NEW PROCESS FOR TITRATING ASTRINGENT SUBSTANCES.

By M. FERDINAND JEAN.

When we pour drop by drop a solution of iodine into any decoction of an astringent matter, previously mixed with an alkaline carbonate, we remark that this solution is absorbed with a great energy. I have observed that the absorption of the iodine takes place, in these conditions, in the direct ratio of the quantity of astringent matter taken, and that 1 part by weight of tannic acid absorbs 4 parts of iodine before we can observe the presence of free iodine in the liquid. It is on this action of iodine on astringent matters that the process of titration is based which forms the subject of this note. The solution of iodine necessary for titrating tannin is obtained by dissolving in iodide of potassium 4 grms. of iodine, and adding to the solution distilled water in quantity sufficient to make a volume of 1000 c.c. To ascertain the value of the solution of iodine, we introduce into a beaker 10 c.c. of a solution of tannin at 0·1 grm. per cent; we mix it with 2 c.c. of an alkaline lye containing 25 per cent of crystallised carbonate of soda; then, by the aid of a graduated burette, we cause to fall into the alkaline liquid the solution of iodine until a drop of the mixture, taken with the glass stirrer and put on a leaf of starched paper, produces a light violet spot, which indicates the presence of free iodine and the end of the operation. The value thus obtained must be corrected, that is to say we must deduct from the number of cubic centimetres of the solution of iodine corresponding to 0·01 grm. of tannin, the volume of this solution, which it is necessary to employ as pure loss before obtaining a coloured reaction on starched paper. For this purpose we measure 10 c.c. of distilled water, which is mixed with 2 c.c. of the alkaline solution; then we pour drop by drop the solution of iodine until we obtain a spot on the starched paper. With a solution of iodine, containing 4 grms. iodine per litre, the correction is commonly from 0·1 c.c., but the greater or less purity of the carbonate of soda may perhaps affect this correction very slightly. For 0·01 grm. of tannic acid dissolved in 10 c.c. of water we must generally use 10·5 c.c. of the solution of iodine at 4 per thousand. Under the influence of iodine the alkaline solutions of tannin, even diluted, take a colouration so intense that it

THE CHEMICAL NEWS.

Vol. XXXIV. No. 884.

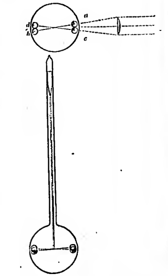
ON REPULSION RESULTING FROM RADIATION.—PART II.*

By WILLIAM CROOKES, F.R.S., &c.

(Continued from p. 176).

90. Experiment proves the above reasoning to be correct. A bulb-tube was prepared in the manner already described (84), but in it were suspended, by separate silk fibres, two glass stems, each having pith balls at its extremity. Fig. 3 shows the elevation and plan of the apparatus. The torsion of the silk fibres was so arranged that the pith balls *a b* hung freely about a millimetre from the balls *c d*. The glass stems were looped in the middle, and bent so that they did not touch each other. After complete exhaustion the following experiments were tried.

Fig. 3.



A beam of radiant heat was concentrated on to the two balls *a c*. When applied momentarily and then removed the radiation simply drove the balls apart, and immediately allowed them to come together again. When, however, the beam was allowed to play upon the balls for about half a minute they became warm and widely separated; and upon now removing the beam of heat the balls did not fall together at once, but took several minutes to regain their original position. This experiment therefore proves Case I.

The bulb and contents being of the ordinary temperature, a spirit-flame was rapidly passed round the bulb to warm it quickly on all sides. The balls were thus in the condition imagined in Case II., being in a space warmer than themselves. They immediately came together, *a* touching *c*, and *d* touching *b*.

Many experiments were tried with the object of proving experimentally the propositions in Cases III. and IV.; but with this apparatus it was found impossible to warm one of the balls without at the same time producing repulsion of the ball by the beam of radiation concentrated upon it. There is, however, little doubt, from the experimental proof of Cases I. and II., that the reasoning is equally correct in the other cases.

91. With a highly exhausted bulb and light pith index, which was found to be exceedingly sensitive to radiation, numerous experiments were tried to see if there was any difference in action between the fingers and a tube of water of the same temperature. Many persons believe that there is a peculiar emanation or *aura* proceeding from the human hand, and Baron Von Reichenbach* considered that he had proved this to be the case. Were this true it was not impossible that the emanation would affect the pith index. I have been unable, however, to detect the slightest action exerted by my own or any other person's hand which I could not entirely explain by an action of heat.

92. A similar series of experiments were tried with various large crystals, which were presented in different ways and with various precautions to the pith index. At first a decided action was observed; but in proportion as precautions were taken to eliminate the effect of heat, so was the action seen to diminish, until very little doubt was left in my mind that the slight residual action would have been entirely stopped had it been possible, with the apparatus then used, to altogether eliminate the action of heat.

93. Attempts were made to see if chemical action would attract or repel the index. I could not, however, produce chemical action close to the exhausted bulb, without at the same time liberating such an amount of heat as to mask any other action.

94. Although I must frequently speak of repulsion by *heat*, and in illustrating any of the results obtained I generally use either the fingers or the flame of a spirit-lamp as a convenient source of radiation, it must be clearly understood that these results are not confined to the heating-rays of the spectrum, but that any ray, from the ultra red to the ultra violet, will produce repulsion in a vacuum. I have already mentioned this fact in my first paper (58, 68). Experiments proving the similarity of action of all rays of the spectrum were shown before the Physical Society on June 20, 1874.† They were, however, tried with a less perfect apparatus than the one I have since used for the same purpose, and need not be further alluded to till I describe the most recent results obtained with the spectrum (110, 111).

95. Some experiments were tried with the object of ascertaining whether the attraction by heat, which, commencing at the neutral point (30 *et seq.*), increased with the density of the enclosed air, would be continued in the same ratio if the apparatus were filled with air above the atmospheric pressure. Two bulbs containing ivory needles suspended by silk fibres were accordingly adjusted to show the same sensitiveness to a hot body. One was

* A Paper communicated to the Royal Society, March 22, 1875. From the *Philosophical Transactions of the Royal Society of London*, vol. clxv., pt. 2.

* "Researches on Magnetism, &c.," translated by Dr. Gregory. London, 1850.

† *Phil. Mag.*, August, 1874.

described in paragraph 102. The beam was of glass, and at one extremity was fitted with a spring clip, also of glass, so that different bodies could be experimented with. Disks of platinum foil, 1 centimetre in diameter and weighing 1·28 grs. each, were prepared, and they were fixed in the clip at the end of the torsion beam, either singly or two, three, or four together, in such a manner that while the disk exposed was always 1 centim. in diameter, the weights should be in the proportion 1, 2, 3, 4. At the other end of the beam a movable counterpoise was arranged, so that the length of beam from the platinum disk to the centre was always the same.

The neutral points were as follows:—

No. of Disks.	Barometer.	Gauge.	Diff. = Neutral point.	Differences.
1.	760	682	78	
				8
2.	760	690	70	
				16
	760	706	54	
				24
	760	730	30	

114. Two pieces of platinum, *a* and *b*, were now cut from the same sheet, each having 1 square centim. of surface. *a* was left the full size, but *b* was carefully folded in four, so as to expose a surface of only a ¼ of a square centimetre, the weight remaining the same. The neutral points were then taken. The average of several observations (which, however, were not quite so concordant as could have been wished) were, below a vacuum,

a.	*b.*
136 millims.	70 millims.

The pieces of foil were then coated with lampblack, and observations again taken. This time the neutral points came out—

a.	*b.*
66 millims.	124 millims.

An intimate connection is thus shown to exist between the absorbing (and radiating) power of the surface on which radiation falls and the atmospheric tension at which the movement is reduced to a minimum. Further experiments on this subject are in progress.

(To be continued.)

NOTE ON ATACAMITE.

By T. C. CLOUD, A.R.S.M.

This mineral is found in large quantities in this district, and some mines have produced magnificent specimens. In many cases it is evident that this mineral has been formed from the oxide most probably by the action of salt water. I have specimens in my possession consisting of a central portion of massive cuprite with crystals of the same, the whole being converted to a depth of about 0·1 inch into atacamite.

When this mineral occurs in contact with limestone rock near the surface of the country it is invariably converted more or less into green carbonate of copper; in some cases this change has only extended to a slight depth, while in others the whole mass is thus converted.

The following are the results of an analysis of a well crystallised specimen of atacamite from this district (Yorke's Peninsula).

Copper	13·73
Chlorine	15·38
Protoxide	55·91
Insoluble residue..	1·47
Water, by difference	13·51
	100·00

The crystals selected for the analysis were about ⅛ inch long, of a clear dark green colour, and perfectly transparent.

It was desired to ascertain the combined action of heat and air on oxychloride of copper. For this purpose a portion of the substance employed in the above analysis was placed in the centre of a combustion tube between two plugs of asbestos; air from a gas holder was passed slowly through the tube, while the latter was heated gradually up to the highest temperature obtainable with a charcoal combustion furnace. This temperature was maintained until the sublimate did not appear to increase further in quantity. When cold the contents of the tube were examined. At the cooler part of the tube a sublimate had formed varying in colour from light yellow to dark brown. On examination this proved to be subchloride of copper. In the place of the original substance there remained a brilliant black fritted mass of protoxide of copper. The internal portion of the tube extending for a short distance from the point where the original substance was placed, towards that part of the tube where the sublimate had formed, was converted into a bluish green glass. At the commencement of the experiment, when the temperature was comparatively very low, oxygen was evolved. I do not know whether this reaction has been noted before, but it is readily observed on heating a small portion of atacamite in a test-tube.

The experiment detailed above was repeated, the atacamite powder in this case being placed in a platinum boat, all the other conditions remaining the same; the results were identical with those obtained in the former experiment. The reaction which takes place when oxychloride of copper is heated with access of air would therefore appear to be as follows:—

$$CuCl_2+3CuO+4H_2O=Cu_2Cl_2+2CuO+O+4H_2O.$$

BUTTER ANALYSIS.
AN IMPROVED METHOD OF ASCERTAINING THE SPECIFIC GRAVITIES OF FATS.

By C. ESTCOURT, F.C.S.
Analyst to the City of Manchester, Borough of Oldham, &c.

The great advance which has been made in food analysis since the passing of the "Food Adulteration Act of 1872" is nowhere so apparent as in the methods employed to detect adulterations in butter. It is scarcely three years since the time when the only methods of butter analysis, so-called, consisted entirely of smelling and tasting. Thus we had a butter taste, a tallow taste, and a lard taste. The first advance made was the observations of the fusing-points of different fats, and the next one was the estimation of the fatty acids present in fats of various origin. The last named process has, since its discovery by Messrs. Angell and Hehner, been so elaborated by various workers, amongst whom are Drs. Dupré and Muter, that nothing further in this direction can be expected.

The process, however, which recommends itself by its simplicity, and its good results, if properly carried out, is that of taking the specific gravities of various fats, butter fat amongst others. This process, devised by Mr. James Bell, F.C.S., principal of the Inland Revenue Laboratory, has only been slightly modified since its first application. The modifications were the change of temperature in the water used to compare with the fat, and the use of specific gravity beads.

In ascertaining the presence of, and estimating the quantity of foreign fat in butter by either the fatty acid, or the ordinary specific gravity method, several difficulties present themselves. In the first

THE MECHANICAL ACTION OF RADIATION.

By LeRoy C. Cooley, Ph.D.

[Read before the Albany Institute, February 1, 1876.]

Sc. Am. Apl/76

The motion of light bodies under the influence of radiant heat and light seems to have been noticed, independently, by several observers, at long intervals during the last half century, but only within the half decade just past can it be said to have gained a place among the phenomena of acknowledged interest in science.

In the *Edinburgh New Philosophical Magazine* for 1828 is a record of what seems to have been the earliest experiments on this subject. They were made by Mr. Mark Watt, and I quote from his interesting paper the following description of the first instance of a light body indicating, by its motion, the impression it received from the sun's rays. "Twelve or fifteen magnetized sewing needles were stuck into a thin circular slice of cork an inch in diameter, at a distance of one sixth of an inch from each other. The heads of the needles were so fixed into the piece of cork that they stood perpendicularly and all the points, being south poles, stood uppermost. The cork was then placed on the centre of a surface of water 1½ feet in diameter. The needles, in this situation, being prevented from evincing any polar attraction by their perpendicular position, were attracted by a moderate degree of light, heat, or electricity, but were repelled by the more powerful impulses imparted by the concentration of any of these bodies.

After the elapse of twenty years the phenomenon seems to have been rediscovered by Mr. Mitchel. A description of his experiment may be found in the first chapter of *Dick's Practical Astronomer* (see also *Scientific American*, vol. xxxiii. 9), and reads very much as follows:

A plate of very thin copper, an inch square, was fixed upon the end of a fine wire ten inches long. A very delicate magnet was fastened to the middle of the wire and the whole, balanced on a pivot, was enclosed in a glass case. The rays of the sun, collected by a concave mirror of two feet diameter, were thrown to a focus on the copper plate. The plate began to move under the influence of the condensed sunbeam, and in about two seconds it had traversed as many inches and struck against the side of the box. This experiment was made with a view to prove that "Light, though exceedingly minute, has a certain degree of force momentum."

Many years later—it was in 1863—the energy of radiation seems to have revealed itself anew to the eminent Prof. Joule. "By means of a cylindrical glass vessel, divided in a vertical direction by a blackened pasteboard diaphragm, which extended to within one inch of the cover and of the bottom of the vessel, and in the upper of which spaces was delicately suspended a magnetized sewing-needle furnished with a glass index, he was able to detect the heat from a pint of water heated to 30° C., placed in a pan at nine feet distance; also that of a moonbeam admitted through an opening in a shutter as it passed across his apparatus." This description is extracted from a lecture by the Earl of Rosse on the heat of the moon, given at the Royal Institution in May, 1873.

In April, 1873, ignorant of all these earlier observations, I read, in this room, a paper on "Convection applied to the Detection of Heat," showing that a delicately-suspended needle would move in obedience to slight changes of temperature in any body brought into its vicinity, and describing a *Thermoscope*, quite sensitive, acting on this principle (*Journal Frank. Inst.*, vol. lxvi. 313). Further experiment soon afterwards resulted in the construction of an instrument so sensitive that the needle would swing in response to the heat radiated from the face of a person sitting at a distance of thirty feet (*Jour. Frank. Inst.*, vol. lxvii. 408). The form of instrument finally adopted, and used also in experiments to be described in the sequel, may be briefly described as follows: In a chamber whose walls are, to a considerable degree, impervious to heat, a glass thread, very long and very light, is suspended horizontally by means of two parallel silk fibres eighteen inches in length. One end of this a slender needle carries a small vertical disk of paper. The small end of a conical metallic reflector passes through the wall of the chamber, and its opening is covered with a piece of thin, partially-charred paper. The radiations from any distant source of heat are concentrated upon this scorched paper by the reflector. The needle-disk is on a level with the lower part of this paper, and moves toward or from it under the influence of every change of temperature it experiences, approaching if it be warmed and receding if it be very gently cooled, but approaching when the reduction of temperature is considerable.

In the meantime Dr. William Crookes, "while weighing heavy pieces of glass apparatus in a chemical balance enclosed in an iron case from which air could be exhausted," noticed that "when the substance weighed was of a temperature higher than that of the surrounding air and the weights, there appeared to be a variation of the force of gravitation." His first paper was sent to the Royal Society in May, 1873. "Experiments were thereupon instituted with a view to make the action more sensible and to eliminate sources of error."

By ingeniously devised apparatus Dr. Crookes was able to subject light bodies to the action of radiant heat and light in a vacuum perfect, doubtless, beyond precedent. While the exhaustion proceeded he found the motion of his slender balance-beam to be towards the source of heat, until, a very high degree having been attained, the motion *turned the other way*, the light body recoiled from the source of radiation as if driven by a delicate repulsion. (See *Quarterly Journal of Science*, 1875.) His second paper communicated to the Royal Society the interesting discovery of the mechanical effect of radiation in a vacuum, and *Repulsion by Radiation* is a phrase describing a new-found fact in physical science for which we are indebted to this capital research of Dr. Crookes.

These experiments of the English scientist, pronounced, by the President of the Mathematical and Physical Section of the British Association, to be among the most interesting in the whole range of physical science, have attracted much attention to the phenomenon. Prof. Dewar in Scotland and Herr Neesen in Germany have made valuable additions to the experimental data.

Prof. Dewar employed a novel means of obtaining the necessary vacuum. When the pump refused to reduce the tension of the rarefied gas, the residue was removed and the vacuum perfected by the absorbent power of charcoal. The vacuum thus obtained, like that of Mr. Crookes, forbade the passage of the induction-spark, and so sensitive was his instrument that "an ordinary lucifer-match held at a distance of four feet produced instant action, which was observed by means of a telescope." (*Nature*, xii. 217.) Of his results more is to be said as we proceed. Herr Neesen's apparatus consisted of a rectangular case of sheet-iron with an aperture in one side closed by a glass plate near to which hung a small and delicately-suspended mirror. The radiations were received by the glass plate, through which they passed to fall upon the mirror beyond, and the mirror was compelled to turn in obedience to their influence. (*Nature*, xiii. 10.)

By the experiments of these several observers it is well established that very light and mobile bodies are affected quite differently by radiant heat or light according as they are suspended in air or in vacuo. *Attraction* in air and *repulsion* in vacuo, are the terms employed by Mr. Crookes to describe these effects. These terms are convenient, but unobjectionable only when we use them to indicate the *direction* of the motion and not to describe the nature of the forces acting to produce it.

Of the nature of these forces views are not yet in accord. Mr. Crookes considers the air-current theory as altogether incompetent to account either for the attraction or the repulsion, but awaits the accumulation of all the facts before attempting to explain any of them. Professor Dewar regards the *heating of the movable disk* as the cause of the motion. He is reported as saying that "While the action takes place in air of ordinary density it is probably due to air currents" but, from the report, he seems not to have based this opinion upon any direct experimental proof. Nor does he allow the repulsion in vacuo to be due to any new forces of repulsion; he attempts to refer it to the molecular energy of the minute residuum of gas still left in the most perfect attainable vacuum. "What takes place," he says, "is this, the particles are flying in all directions with velocity depending upon the temperature. When they impinge against the heated disk their velocity is increased. They go off with a greater velocity than those which go off from the colder side, and hence there is a recoil of the disk." And this recoil, he thinks competent to put the disk in motion even in his excellent vacuum, "where we know that the exhaustion has reduced the density to $\frac{1}{20,000,000}$ of its original."

Professor Osborne Reynolds claims that whenever a surface imparts heat to a gas, there must be a reaction of the gas against the surface. A surface free to move would be propelled by this reaction. Moreover in a vacuum this motion would encounter less resistance and hence would be more conspicuous, as if it were due to a stronger force. Repulsion in vacuo, according to this view, is the effect of this gaseous reaction. (*Nature*, vol. xii. 403.)

If others have engaged in the investigation of this interesting subject, their work has, down to the present time, escaped my attention.

In July, 1875, I read a paper before the *Poughkeepsie Society of Natural Science*, giving a synopsis of several series of experiments, some of which were made before the publication of Mr. Crookes' remarkable discovery, but many of them afterward, with a view to determine the nature of the force as far as the so-called attraction in air is concerned. (*Jour. Frank. Inst.*, vol. lxx, 134.) The points then made are these: 1st. The motion of the needle having proved to be, under a great variety of conditions, exactly what air-currents are competent to produce, we may justly infer that it is due to convection. 2d. If this motion shall cease to occur when the air is removed (and Mr. Crookes has proved that it does), the evidence in favor of convection is complete.

Whatever may be the nature of the repulsion in vacuo, convection will, doubtless, in the end, be admitted to be the cause of the motion in air. The two motions are, I am persuaded, altogether distinct phenomena manifestations of two antagonistic forces, the repulsive being the more delicate and able to produce its effect only when the overwhelming power of convection currents is overcome by perfecting the vacuum.

But there is another phase of this curious action which seems to have escaped the notice of former observers. It may be described as *repulsion in air*. The application of a very gentle heat will, under certain conditions, drive the disk away from the warmed surface, even in air of ordinary density.

At intervals, from the time of my earliest experiments, this puzzling motion would thrust itself before me until I was convinced that it was not an experimental accident but that it was a legitimate effect of some rare combination of conditions. What these conditions are I set myself to discover.

It was an effect which I could not, at first, produce at will. Sometimes it would appear in the early morning but refuse to be reproduced as the day advanced. Sometimes it would occur in the evening when no trace of it had been seen during the day. A day of alternate showers and sunshine seemed to be most favorable to its production. Remembering that the walls of the chamber were to a considerable degree impervious to heat, so that the temperature within suffered no rapid changes as did that without, these facts suggested the direction in which to seek for the cause of the action. By inserting a thermometer into the chamber and placing another outside, the difference of temperature between the interior of the instrument and the air outside could be measured and its relation to the motion of the needle could be studied. A multitude of observations followed. In every case when the repulsion occurred the temperature of the interior of the chamber was found to be higher than that of the external air. With a difference of a single degree (F.) the needle would be repelled by the gentle heat of the hand held at a distance of twelve inches, while by a somewhat stronger heat the motion would be reversed. With a larger difference of temperature the repulsion would respond to a greater heat, becoming attraction again, however, if a certain limit of intensity was passed. Such observations finally revealed the necessary conditions. Repulsion in air occurs when: 1st. The temperature of the interior of the instrument has been for some time a little higher than that of the external air; and 2d. The degree of heat applied is appropriate to this difference of temperature.

The next step was to carefully determine the place of the zero of the needle scale. Call to mind the arrangement. The slender needle is suspended horizontally by two parallel silk fibres. The torsion of these fibres is a delicate force tending to hold the needle in a certain position. The place of the disk thus held at rest is the zero of the scale. Now the swinging of the needle toward the zero can indicate no positive action of any force other than the torsion of the fibres. Its swinging away from zero, however, can be due to nothing less than some positive force which overcomes the torsion. Having determined the place of the zero, repeated observation showed that the repulsion was real, since the needle moved beyond its zero in opposition to the torsion of its fibres.

In explanation of this curious effect I offer the following suggestions. It is well known that a cooled surface will cause a downward air-current in contact with it, and again that heat being applied will reverse the direction of this current. But this reversal can not be effected instantaneously. The effect of a *gentle* heat will be first, to *slowly* neutralize the cold and thus *gradually* diminish the downward current, and second, afterward to produce, as gradually, a current upward. Now while the cold current is being neutralized, the torsion of the fibres will carry the disk to its zero and when the upward current is established the disk will be again wafted toward the warmed surface. But if this transition from a downward to an upward current is very slow there must be an appreciable time when there is equilibrium, when the air is in contact with a surface warmer than itself and yet for a brief period is free from convection currents.

Again it is well known that the air is perfectly elastic and further that an elastic body will transmit the energy of blows which do not put its mass in motion. Then let us conceive a mass of air, lying between the disk and the surface which receives the heat, subjected on the surface side to a temperature higher than its own and yet free from convection currents. Under these conditions the elastic medium must transmit the heat energy to the disk in a manner not altogether unlike the transmission of the force of a blow by a series of elastic balls. As I conceive the molecular motion it is this. The molecules of air are in motion with a velocity depending upon temperature. When they impinge against the warmed surface they are thrown off with an increased velocity. This velocity is transmitted until the molecules in contact with the disk receive it and they strike the disk with greater energy than do those against the opposite side. This excess of energy drives the disk along.

If this explanation is correct then while the attraction in air is the manifestation of the well-known convection currents, this repulsion in air is the manifestation of *a molecular transmission of energy* by the air in straight lines outward from a heated surface. Now if such a molecular action do exist, then a light body near a heated surface must, in every case, be subject to the influence of these antagonistic forces, being solicited toward the heat by convection, and repelled from it by the energy transmitted. Because convection is the more powerful, the motion is toward the source of radiation, except when by careful choice of conditions the delicate repulsion can be made visible.

Whether this repulsion in air is at all related to the repulsion in vacuo, I am not prepared to consider clear. The effect of exhaustion, on the relative strength of these two forces, is, however, an interesting point in this connection. In a good vacuum the power of convection must be vastly reduced and as the vacuum approaches perfection, this power must approach annihilation. On the other hand nothing short of an absolute vacuum can forbid the molecular transmission of energy. It seems highly probable that at a certain high degree of exhaustion this molecular energy would be the more powerful of the two, and hence that repulsion would be the normal instead of the exceptional indication of the instrument.

"WEIGHING" A BEAM OF LIGHT.

On Friday last Professor Crookes, F.R.S., fulfilled a promise previously made and much discussed in scientific circles by "weighing" a beam of light in the presence of a distinguished audience at the Royal Institution. The general interest which the recent discoveries of Mr. Crookes have excited could not have been better testified than by the crowded state of the lecture room on this occasion, for the fog was so dense that coachmen had to descend from the box and grope their way to Albemarle-street by the aid of lanterns. This practical recognition of the exceptional importance of the evening's work was especially pleasing to the friends of Professor Crookes, though probably a matter of indifference to himself, for it is but too notorious that the originality of some of his collateral researches has raised up a little band of detractors. Few scientific men have the courage of their convictions to the same extent as Mr. Crookes, who we have little doubt would join without hesita-

tion in an incantation scene or dance round Macbeth's cauldron, impervious to ridicule, if he had reason to believe that ever so little territory might thereby be won or reclaimed from the unknown land. Both at the commencement and the end of his address the lecturer very properly directed attention to the fact that the discovery of the remarkable phenomena submitted to the audience was due simply to his having followed upon the clue afforded by an apparently insignificant anomaly. We think there must have been an unpleasant, though unintentional, sting in these words to some present, for there were amongst the listeners one or two science popularisers, pets of society, who had somewhat ostentatiously slighted the discoveries at first, but would now give their ears to be able to "stump the provinces" with the radiometer as a child of their own, and there were others present who had also taken little pains to keep out of Goldsmith's category of "fools who go to scoff."

Desiring to weigh some small quantities without the disturbances inseparable from the operation as ordinarily conducted, the lecturer stated that he made arrangements to do the weighing in a vacuum, but was surprised to find that he had apparently called into existence another set of disturbing causes no less embarrassing than the former, since upon approaching a light to the exhausted vessel the action of gravitation appeared to be appreciably modified. Professor Crookes at once set to work to determine the general conditions and intensity of this new force, and his investigations have culminated in the experiment performed on Friday evening last, when he weighed the pressure resulting from the light of a standard candle 6 in. off, falling upon a surface *in vacuo*, 2 square inches in area. It was thought at first that the force to be measured must be inconceivably small, so a horizontal pendulum of extreme sensitiveness was constructed, so sensitive, in fact, that as Mr. Crookes graphically put it, by changing your position in a room you altered the centre of gravity of the whole house, and so threw out the readings of the instrument. The horizontal pendulum then was incapacitated from *trop de zèle*, but a suitable servant was found in the torsion balance, which as first constructed consisted, we believe, of a flat bar or index of pith suspended by a cocoon fibre. When one-half of each face of the index was blacked on alternate sides of the vertical centre line, and the apparatus was placed in the light, rotation commenced and continued until the torsion of the fibre caused a retrograde movement. From this movement to continuous rotation was only a step, but it was a step which placed the world in possession of the now famed "radiometer" of Professor Crookes.

In its simplest form the radiometer consists of two cross-arms carrying at their extremities four pith discs blackened on one side, delicately balanced on a vertical pivot, and enclosed in a glass vessel exhausted to as perfect a vacuum as can be obtained by any known means. At the lecture on Friday the rotation of an instrument having alternate circular and star-shaped pith discs was very effectively shown by projection on a screen. When the heat rays of the electric light were cut off by the interposition of an alum solution, rotation still continued, but at a decreased velocity. Experiments have been made by Mr. Crookes to ascertain the relative influences of the different coloured rays of the spectrum upon the rotation of the radiometer, and a diagram of the results was exhibited. It was found that the ultra-red rays were the most powerful of all—a not altogether surprising result when it is remembered that the emission of heat from those invisible rays is nearly eight times the entire luminous emission. Numerically expressed the dynamic force of the ultra-red rays being 100, that of the violet rays is 6 only, and it would appear that the experimenter considers the dynamic force of the rays to be simply proportional to the revolutions of the radiometer, although it would have appeared more probable that at least an appreciable portion of the resistance of the instrument would have increased as the square of the velocity.

The relatively small effect of the interposition of coloured glass on the speed of rotation was well shown by a radiometer having a mirror at its centre, which caused a dot of light to describe a circle on the ceiling of the theatre. At first it was thought that great lightness of construction was essential, but here we have a radiometer carrying a mirror, and if a mirror why not a magnet? Such was the reasoning which led the professor to the construction of the instrument, which with good grounds he

32

SOME RECENT RADIOMETRIC EXPERIMENTS IN GERMANY.

76

SINCE the radiometer was described by Mr. Crookes, it has been the subject of a large amount of observation, both in this country and on the Continent. We propose here to give a short account of two series of experiments lately made with it in Germany, where it generally passes under the name of the "Lichtmühle," or light mill. They appear to give some useful aid towards comprehension of the action of this somewhat enigmatical apparatus. The radiometers used were of the kind constructed by Geissler, of Bonn. They are wheel-shaped, the wings consisting of small leaves, apparently of annealed mica, blackened on one side with lamp-black; they are connected by platinum wires with a small cap, which turns on a fine needle point. The mill is enclosed in a vessel of thin glass, in which the air has been rarefied as much as possible. One series of experiments is that by M. Wartmann, described in the *Archives des Sciences* for March; the second by M. Weinhold, in *Carl's Repertorium für Experimental Physics* (Bd. xii., p. 105).

M. Wartmann had two radiometers, the one, A, with square, the other, B, with round wings. If both are exposed to the action of flame, or a glowing metal, or dark heat from as intense source of heat, they move with more or less rapidity, and the black surface is repelled. This may be called the "direct" rotation. The same occurs when the rays fall only on the black surfaces of the wings. On the other hand, there is a distinct difference between A and B, when the black surfaces are covered and the others exposed to the sun. While A shows a slow, direct rotation, B shows a distinct reverse rotation. In order to obtain this reverse rotation with A, the sunlight must be concentrated with a lens, and made to fall on the uncovered surfaces, while the blackened surfaces are very carefully protected against any radiation. If a less energetic source be made to act on B—namely, a glowing platinum spiral or a moderator lamp—then, without a lens, the reverse rotation is obtained slow and discontinuous; but it can be obtained easily, if two sources are used, acting in opposite directions on the uncoated surfaces, at the two ends of a diameter. If the source be removed, or its energy diminished, the motion of the mill takes place in a jerking manner. The velocity is greatest if the plane of the wing stands at right angles to the line of shortest distance from the source of radiation, the velocity diminishes with increasing obliquity of the repelled wing, then it becomes greater at the moment that the following wing receives the heat rays at a right angle.

On the two opposite surfaces of the same wing of B are concentrated by similar lenses the rays from two moderator lamps of the same calibre. By changing the distance of the lamps, one may succeed in entirely neutralising their opposite actions. The action exerted on the black surface is then 11.9 times weaker than that on the white surface, "whence it follows, that to obtain equilibrium the intensity of the pressure must be in inverse ratio of the power of absorption. The least change of the distance, or the energy of the lamps, renews the motion." In a horizontal plane, and concentric with the radiometer, was placed an iron ring which had been raised to a red heat. Forthwith the rotation began, and it became very strong if the plane of the ring coincided with that of the arms. At equal distances above and below from this plane the velocity is the same. The radiometers were placed in a blackened case, which was perforated with an opening above. By means of a mirror a thin bundle of sun rays was reflected vertically and parallel to the plane of the wings. There always occurred a direct motion, whether the light was directed before the white or before the black surface; in the latter case the motion appeared to be quicker. If a moderator lamp be used instead of sunlight, the rays must be concentrated with a lens. The interposition of a very transparent plate of alum weakens to a great degree the action of a good lamp on A and on B. "The two radiometers are unresponsive to the largest sparks of a Ruhmkorff coil or a Holz machine, but the wings are distinctly attracted on approximation of an electrified body. In the magnetic field of a large electro-magnet, the mills show the ordinary actions of induction. In water of 13 deg. within a cylindrical glass vessel A behaved as in air, but its rotation was under these conditions slower. The radiometer B, on the other hand, showed the reverse rotation when the rays of a strong moderator lamp were concentrated with a lens on an uncoated wing. If the water in which the instruments are be heated to 60 deg., they remain motionless. When the radiometers are placed over a stream of heat, for example, an alcohol lamp with flue, the rest or motion of the mills is no way affected. When, however, the rising stream of hot air has raised the temperature of A to melting of the shellac on the point of the apparatus, the mill moves a little with frequent intermittence, and at length shows a slow, direct rotation. This suddenly ceases if the source of heat be removed, and it is slowly reversed during the first phases of cooling.

"The difference," M. Wartmann observes, "in behavior of the two radiometers, could not arise from the unequal surface of their wings. It appears to me rather that in the interior of B the rarefaction of air had not been carried so far as in A. Further, the white surfaces of B have a higher polish and brightness than those of A, their power of reflection must therefore be greater. These various experiments appear to confirm the view which attributes the movements of the mills to the expansions of the gaseous bodies under very weak pressures." The experiments made by M. Weinhold had the direct object of testing the different explanations that have been offered of the phenomenon. He, therefore, made a number of changes in the radiometers, some of which we shall notice. He first convinced himself that different specimens of the instrument are sensitive in quite different degrees to radiation of varying strength; and, therefore, that the wheel-shaped radiometer is not directly reliable as a measuring instrument for the strength of the radiation. M. Weinhold obtained radiometers which ran backwards on the radiation being cut off by using transparent mica leaves instead of the annealed and untransparent ones. If such an instrument be exposed a few seconds to strong radiation from a gas flame, and the flame be then removed, the mill first comes to rest and then begins to make a number of rotations in the opposite direction. This backward motion, however, is not due to action of backward radiation through the mica; for on interposition between the four wings of four now unblackened wings, consisting, in one case, of transparent mica, and in the second of annealed mica, the backward motion occurred in both cases. It is more probable that the backward motion is simply a consequence of radiation of the blackened surfaces, but that it only occurs when the wings have sufficient capacity for heat and conducting power. Indeed, radiometers with wings of magnesium metal show the backward motion in a remarkable manner. Some further modifications of the radiometer by inclination of the wings to the horizon, and by alternate use of blackened and unblackened annealed and transparent mica-leaves—for particulars of which we must refer to the original—convinced M. Weinhold that the motion is neither due to currents of minute quantities of gaseous matter, nor to the impellent force of evaporating water. It is rather, he thinks, due to some action—yet to be elucidated by experiment—of rays absorbed by the surfaces, and is in proportion to the amount of this absorption.

ROYAL INSTITUTION. 76.

The Mechanical Action of Light.

AT the Royal Institution on Friday last, Mr. Crookes, F.R.S., delivered a lecture on "The Mechanical Action of Light." Mr. Justice Grove presided, and among the listeners were Professor Tyndall, Dr. Frankland, F.R.S., Prof. W. K. Clifford, Mr. William Spottiswoode, F.R.S., and Mr. Warren de la Rue, F.R.S. The experiments were of an unusually complicated and delicate description; and in their performance the lecturer was aided by Mr. C. Gillingham and by his son, Mr. Henry Crookes. Mr. Crookes said that all the physical forces render their action perceptible by the production of motion, but that light had never been directly converted into mechanical motion until the experiments had been devised which he had to bring before them that evening. Once in attempting to weigh bodies in an approximately perfect vacuum, he witnessed anomalies for which he could not account, but upon which information had been thrown by his more recent discoveries. He found, as published some time ago, that the light of a candle would attract an arm of pith suspended in an imperfect vacuum, but repel a similar arm suspended in the very perfect vacuum obtainable only by the aid of the Sprengel pump. Of this pump he exhibited a most perfect and improved specimen, so perfect that it would produce a vacuum through which the electric spark would not pass. In all his experiments he had been indebted, to a very great extent, to the industry and marvellous powers of glass-blowing possessed by his assistant, Mr. C. Gillingham. He then described the construction of his "radiometer," and stated that the propelling force of light was not so weak as he had once supposed. Instead of radiometers in which all the moving parts weighed sometimes as little as a quarter of a grain, he found that he could make the instruments to carry little magnets, and he exhibited one in which ten discs of pith were required to carry round one magnet. Outside the bulb of this instrument was a magnetic arm, which was attracted every time one pole of the magnet inside the bulb came near it, and the consequent "bowings" of the magnet outside were made to convey electrical impulses to a Morse telegraphic instrument, whereby a series of dots was made upon a slip of paper, and the more rapid the rotation inside the bulb the closer together were the dots. Thus his radiometers had been made self-registering and suitable for meteorological purposes. He also pointed out that no good photometer had ever been made, and he exhibited apparatus infinitely more exact for measuring the illuminating power of gas, or any kind of light, than those founded upon the supposed unvarying illuminating power of the very untrustworthy "standard candle." After many experiments, magnified and projected on the screen by the aid of the electric lamp, he exhibited one of his latest, in which he directly measured the mechanical force of the impact of light, not its weight, for the experiments did not remove light from the class of imponderables. By means of the force of torsion of a filament of glass, brought into play against an iron weight of one-hundredth of a grain, all in vacuo, he could so adjust a mirror to a zero point that it would move when parts of the apparatus were submitted to the action of light; thus, he proved that the push of a candle six inches off amounted to ·00162 grain. By calculation he estimated that the pressure of sunlight on the earth was not less than 2 cwt. per acre, 57 tons to the square mile, and 3,000 millions of tons upon the whole earth, all this power acting in opposition to the force of gravitation. In conclusion, he said that all the results he had exhibited had been obtained in consequence of his examination of an anomaly contrary to all ordinary experience. Anomalies were of the utmost value to men of science; they were gateways leading to new researches, and to the establishment of new relations.

THE RADIOMETER.

[10395.] 76 THERE is a very simple method for demonstrating the repulsive action of heat upon both the bright and the blackened sides of the radiometer vanes, and at the same time the preponderating influence it exerts upon the most actively radiating surface of the two, which I have not yet seen noticed. It is this: the radiometer being at perfect rest, and the radiant heat from the body and face of the observer being cut off by the intervention of a glass trough containing a saturated solution of alum in water, or something equivalent, press the warm finger and thumb on opposite sides of the vacuum globe. One of the black surfaces will be repelled from one warm point, until a bright surface advances to the opposite point, when that, too, will be repelled as it approaches; the action will then be repeated, and an oscillating movement kept up, until sufficient momentum has been acquired (from the stronger repulsion of the black surface) to force the bright surface of the vane past the dead point as it were, when complete rotation will take place.

Your correspondent, "B. P. A." (10369), seems to have no notion of even the elementary conditions necessary for experimenting on the radiometer with light rays. Hence perhaps his nervousness about Mr. Allen.

H. C. Koy.

THE RADIOMETER.

THE following curious experiment with the radiometer has been lately made by M. Ducretel. When it is rotating as usual in ordinary daylight, some ether is poured on the envelope; the direct rotation stops, and inverse rotation occurs. This reaction presently ceases, and the vanes resume the original direct rotation, notwithstanding the evaporation kept upon the envelope by light sprinkling of ether. The rotation now, however, becomes faster than at the first, the evaporation apparently acting like a source of heat, though it perceptibly cools the envelope. When the sprinkling of ether has stopped, the movement resumes its normal velocity, and remains direct. M. Ducretel also tried the effect of phosphorescent powders presented before the radiometer in darkness, after they had been exposed to sunlight; but the instrument showed no motion. The chief objection brought against the emission-theory explanation is that the white face, reflecting the light and behaving like an elastic surface, should be more strongly repelled than the black. M. Giffard illustrated this by letting a small piece of agate fall from a constant height on one plate of a balance. The depression is much greater when the plate is of annealed steel—that is, elastic or like the white face—than when it is of copper and like the black. But M. de Fonvielle remarks that this is supposing the velocity of the shock is not superior to the velocity of propagation of the molecular movements. A revolver ball makes a hole in a pane of glass because the molecules directly struck have not time to communicate their motion to neighboring molecules. Now the luminous molecules have a velocity vastly greater than that of the ball. And it is really the degree of absorption, other things equal, that must rule the velocity of propulsion.

LETTERS TO THE EDITOR.

(We do not hold ourselves responsible for the opinions of our correspondents.)

THE MECHANICAL POWERS OF LIGHT.

SIR,—I have read with much interest the article which appeared in your pages on the 13th of April on Crooke's radiometer. I had previously been familiar with all that has been written on the instrument, and I had seen it in action under varying circumstances. It is not too much to say, as you have done, that its phenomena are to the last degree perplexing; but in spite of this circumstance, I feel assured that a consistent theory of this instrument will be produced. Such a theory will be the result, most probably, of the careful study of many minds. My purpose in writing now is to endeavour to clear the ground on a single point connected with the radiometer. I cannot attempt at present to lay before your readers a theory, which, although comparatively satisfactory to my mind, does not as yet admit of verification as a whole. But it cannot do harm, and it may do good, to place a portion of this theory before the world for discussion, and perhaps for refutation.

One of the great difficulties about the radiometer is that the blackened surface of the pith discs retreats from the light. It has been stated that this should not be the case. As bright surfaces radiate light, and blackened surfaces absorb it the pressure of light ought to be greater on the bright than on the black surface. It is perhaps a fortunate circumstance that it is not the foil surface of the radiometer that retreats. If this were the case, a theory which is, I think, unsound on dynamical principles, would have been accepted as correct, and error would have been propagated and inquiry checked.

I am about to show that, so far from the metallic surfaces retreating, they are the surfaces which ought to advance. For this purpose I must for the nonce use the corpuscular theory of light; not because that theory is necessarily sound, but because it affords a very easy illustration of the statements I am about to make.

Let us suppose then, that, to use your own illustration, light resembles in its impingement on a body the effect of a handful of small shot thrown forcibly against a board.

To simplify matters I shall deal with only a single light corpuscule, or grain of shot, which I shall style *a*. The energy stored up in *a* is represented at the moment it strikes the disc of a radiometer by $\frac{W v^2}{2g}$.

Let us assume that our light-corpuscule is infinitely elastic, so elastic that the elasticity of the foiled face of a pith disc is as nothing. The latter may, therefore, as compared with *a*, be regarded as infinitely hard and impenetrable. Now it may be shown, that if an infinitely elastic body strikes an infinitely rigid body, the elastic body—in this case *a*—can do no work upon it. For let us suppose that *a* weighed a pound, and fell on a rigid surface from a height of 10ft., all resistance of the air, &c., being removed, then the ball would rebound to a height of 10ft., and under the conditions, it would so continue to fall and rebound to all eternity, and no work of any kind could be done on the rigid surface.

From which it appears that light-corpuscules impinging on a foiled disc rebound from it and do no work upon it. They transfer none of their energy to the disc.

Now let us suppose that a light-corpuscule falls upon a surface which is yielding or inelastic. The corpuscule in such a case cannot rebound. It is fixed and held fast in, so to speak, a viscous medium. Under such a condition, the whole of the energy $\frac{W v^2}{2g}$ stored in a corpuscule must either be wholly transformed into heat, or into work, or into motion. In any case, the energy in the corpuscule is transferred to the medium in which its progress has been arrested. Now the blackened disc of the radiometer is the medium which stores up all the energy put into it by the impact of light corpuscules, while the foiled surface stores up none of the energy contained in the infinitely elastic light corpuscules. Consequently the blackened surface, continually receiving force always in the same direction, retreats from the impact of light, while the foiled surface of the disc remains unaffected by the impingement of rays, which retain all the force they originally possessed after they have struck it.

To show that this theory is consistent with known laws, I shall go a step further, still retaining, without prejudice—to use a legal phrase—the corpuscular theory. I have shown that the energy stored in a corpuscule must be converted into heat or motion if the motion of the corpuscule be destroyed. Now what do we find to be a fact in nature? Bright surfaces which reflect light well, are not heated by the sun's rays as fast as darker surfaces. Let us suppose that the sun gives off no heat, that its energy is displayed in imparting motion to countless millions of corpuscules of light, and light alone. Strange as it may appear, it is possible to conceive of a body being raised through successive conditions of vibration, until such an exaltation is at last reached that nothing is given off but light. If my readers will excuse a paradox, we may suppose that a body is heated so intensely that it ceases to be hot, and gives off light alone. Assume this to be the condition of the sun. We have then countless myriads of corpuscules impinging on the surface of the earth, and doing what? Those which fall on surfaces impenetrable and hard to them, are in no wise affected, therefore such surfaces remain cold. This is the case with a plate of polished silver placed in the sun—it reflects the sun's rays and remains unheated. If it were absolutely hard and bright it could not be raised in temperature at all. No work is done on or in the plate; the motion of the corpuscules is undestroyed.

But what happens if we place a blackened surface in the sun? The corpuscules impinging on it have their motion at once arrested. They cannot recoil. Their store of energy is at once converted either into motion or into heat. Motion, save in the radiometer, cannot, in one sense, take place. The result is that we have heat. The black surface becomes warm, but it is not true to say that that warmth has come from the sun, for that would be to say that the sun is hotter to a bit of tin coated with lampblack than it is to a bit of tin highly polished, which is absurd. The sun then gives off energy alone in a form which we call light. This energy is convertible into heat, and it is only so convertible when the substance on which it impinges is in a condition to arrest the movement of the corpuscules, and, to use an engineering phrase, "to take the work out of them." Nor is the phenomenon proper to reflecting surfaces only. Glass is not heated by the sun's rays because the corpuscules can pass through it without loss of motion.

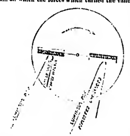
If, then, it can be proved that the impact of light corpuscules is transformable into work in the way I have shown, we have so far a consistent explanation of the fact that the blackened surface of the radiometer recedes instead of the bright surface.

I am well aware that the mere colour alone will not suffice, and that material exercises a considerable influence on the phenomena, but it would be impossible for me to go into these points now. I have sketched hastily certain heads of a theory, which are complete in themselves, although they do not constitute a complete theory of the radiometer. Perhaps some of your readers will point out the weak points in this communication, and so help a fellow worker in the field of science.

Should it appear that my views are on the whole satisfactory, I hope, with your permission, to show in a future letter how all that I have advanced on the corpuscular basis is equally applicable if we accept the received vibratory theory of light. X.

Streatham, May 15th.

SIR,—I was much struck on reading your article on the radiometer in THE ENGINEER of April 14th, by the fact which your note therein that the pith vanes being held by a magnet, the glass envelope rotates. And I would, rather diffidently, as becomes one who has not made the subject a special study, offer the following explanation of the fact. Glass, as everybody knows, is perfectly pervious to light—that is, to the luminous rays of light; but it shuts out those rays which may be called the heat rays of light. Now, lamp-black absorbs the luminous rays of light perfectly, but does not absorb so well the non-luminous or heat rays. Now may not this explain the above phenomenon? For the silvered side of the vane would reflect light, which would readily pass through the glass, while the lamp-black side would only reflect that which would not pass through, but would be checked by the non-diathermanous character of the glass. Now this check to the passage of the rays might cause a repulsion of the blackened vanes, thus causing their rotation; and in the same way, supposing the vanes to be held, the glass would be repelled and rotate; or in other words, the glass is the fulcrum on which the forces which turned the vanes act.



The diagram explains the meaning of my words. Now, it would be easy for Mr. Crookes to test whether this is the case, by using an envelope of rock salt, which is diathermanous to all the rays of heat and light, and if the vanes rotated in this envelope, my explanation falls to the ground. The experiments on which the above assertions are based are those of Melloni on radiant heat, recorded in Ganot's "Physics." I utter this explanation with some reluctance; but, although the way in which I have stated it may not be strictly correct, yet there may be a germ of truth in the idea. Whether it is so, could only be determined by experiments which I have not the means of making. ALFRED CLIFT.

THE CHEMICAL NEWS.

VOL. XXXV. No. 910.

ON
REPULSION RESULTING FROM RADIATION.
PRELIMINARY NOTE ON THE OTHEOSCOPE.*

By WILLIAM CROOKES, F.R.S., &c.

I COMMUNICATED to the Royal Society, in November last, an account of some radiometers which I had made with the object of putting to experimental proof the "Molecular pressure" theory of the repulsion resulting from radiation. Continuing these researches, I have constructed other instruments, in which a movable fly is caused to rotate by the molecular pressure generated on fixed parts of the apparatus.

In the radiometer, the surface which produces the molecular disturbance is mounted on a fly, and is driven backwards by the excess of pressure between it and the sides of the containing vessel. Regarding the radiometer as a heat-engine, it is seen to be imperfect in many respects. The black or driving surface, corresponding to the heater of the engine, being also part of the moving fly, is restricted as to weight, material, and area of surface. It must be of the lightest possible construction, or friction will greatly interfere with its movement; it must not expose much surface, or it will be too heavy; and it must be a very bad conductor of heat, so as to retain the excess of pressure on one side. Again, the part corresponding to the cooler of the engine (the side of the glass bulb) admits of but little modification. It must almost necessarily be of glass, by no means the best material for the purpose; it is obliged to be of one particular shape; and it cannot be brought very near the driving surface.

A perfect instrument would be one in which the *heater* was stationary; it might then be of the most suitable material, of sufficient area of surface, and of the most efficient shape, irrespective of weight. The *cooler* should be the part which moves; it should be as close as possible to the heater, and of the best size, shape, and weight, for utilising the force impinging on it. By having the driving surface of large size, and making it of a good conductor of heat, such as silver, gold, or copper, a very faint amount of incident radiation suffices to produce motion. The black surface acts as if a molecular† wind were blowing from it, principally in a direction normal to the surface. This wind blows away whatever easily movable body happens to be in front of it, irrespective of colour, shape, or material; and in its capability of deflection from one surface to another, its arrest by solid bodies, and its tangential action, it behaves in most respects like an actual wind.

Whilst the radiometer admits of but few modifications, such an instrument as the one here sketched out is capable of an almost endless variety of forms; and as it is essentially different in its construction and mode of action to the radiometer, I propose to identify it by a distinctive name, and call it the Otheoscope (ὠθέω, I propel).

The glass bulb is an essential portion of the machinery of the radiometer, without which the fly would not move; but in the otheoscope the glass vessel simply acts as a preserver of the requisite amount of rarefaction. Carry a radiometer to a point in space where the atmospheric pressure is equal to, say, one millimetre of mercury, and remove the glass bulb; the fly will not move, however strong the incident radiation. But place the otheoscope in the same conditions, and it will move as well without the case as with it. In the preliminary note already referred to*, I described a piece of apparatus by which I was able to measure the thickness of the layer of molecular pressure generated when radiation impinged on a blackened surface at any degree of exhaustion. At the ordinary density of the atmosphere the existence of this molecular disturbance was detected several millimetres off, and its intensity increased largely as the generating surface and movable plate were brought closer together. It would be possible, therefore, to construct an otheoscope in which no rarefaction or containing vessel was necessary, but in which motion would take place in air at the normal density.‡ Such a heat-engine would probably work very well in sunlight.

Aided by the mechanical dexterity of my assistant, Mr. C. H. Gimingham, I have constructed several varieties of otheoscope. These I propose to exhibit at the Soirée of the Royal Society on Wednesday next, as illustrations of the very beautiful manner in which, at this stage of my investigations, theory and experiment proceed hand in hand, alternately assisting each other, and enlarging our knowledge of those laws of molecular movement which constitute a key to the relations of force and matter.

The following is a list of the otheoscopes I have already made, together with some new experimental radiometers, which will be exhibited for the first time on Wednesday:—

1. *Otheoscope.*—A four-armed fly carrying four vanes of thin clear mica is mounted like a radiometer in an exhausted glass bulb. At one side of the bulb a plate of mica blacked on one side is fastened in a vertical plane, in such a position that each clear vane in rotating shall pass the plate, leaving a space between of about a millimetre. If a candle is brought near, and by means of a shade the light is allowed to fall only on the clear vanes, no motion is produced; but if the light shines on the black plate, the fly instantly rotates as if a wind were issuing from this surface, and keeps on moving as long as the light is near.

2. *Otheoscope.*—A four-armed fly carries roasted mica vanes, and is mounted in an exhausted glass bulb like a radiometer. Fixed to the side of the bulb are three plates of clear mica, equidistant from each other in a vertical plane, but oblique to the axis. A candle brought near the fixed plates generates molecular pressure, which, falling obliquely on the fly, causes it to rotate.

3. *Otheoscope.*—A large horizontal disk, revolving by the molecular disturbance on the surface of inclined metallic vanes, which are blacked on both sides in order to absorb the maximum amount of radiation.

4. *Otheoscope.*—Inclined aluminium vanes driven by the molecular disturbance from the fixed blacked mica disk below, blowing (so to speak) through them.

5. *Otheoscope.*—A large horizontal coloured disk of roasted mica, driven by inclined aluminium vanes placed underneath it.

6. *Otheoscope.*—A bright aluminium disk cut in segments, and each segment turned at an angle, driven by a similar one below of lampblacked silver.

7. *Radiometer.*—A vertical radiometer, made with eight disks of mica blacked on one side, and the whole suspended on a horizontal axis which works in two glass cups. The motion of the radiometer is assisted on each side by driving vanes of aluminium blacked on one side.

8. *Radiometer.*—A vertical turbine radiometer, the oval vanes of roasted mica blacked on one side.

9. *Radiometer.*—A spiral radiometer of roasted mica blacked on the upper side.

---

* Read before the Royal Society, April 26, 1877. Received April 23, 1877.

† *Molecular*, not *molar*. There is no wind in the sense of an actual transference of air from one place to another. This molecular movement may be compared to the movement of the gases when water is decomposed by an electric current. In the water connecting the two poles there is no apparent movement, although eight times as much matter is passing one way as the other.

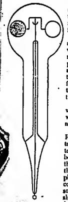
* *Proc. Royal Soc.*, Nov. 16, 1876, p. 315.

‡ Since writing this I have constructed such an instrument. The movement takes place in the way I had anticipated.—W. C., April 28, 1877.

SIR WILLIAM GROVE ON THE RADIOMETER.[1]

77

SIR WILLIAM GROVE described some experiments he had recently made with a modification of Crookes's radiometer. After a few prefatory trials, such as coating one-half of the bulb with tinfoil and electrising it, which gave no notable results, he devised a method, shown in the accompanying sketch, by which he could electrise the whole of the internal system. Four aluminium vanes, each blackened on one side, had metallic arms and a metal point at their crossing that rested in a metal cup. The latter was united to a platinum wire that passed through a glass tube and was fused into it, the platinum wire protruding. Lastly, the glass tube was fused inside the apparatus and hermetically sealed, the end of the platinum wire being exposed. The vacuum in this apparatus was considered by Mr. Crookes[2] to be as perfect as in his radiometers generally, but Sir William Grove doubted that it was so. The following were the results:—



1. With the faint light of a lucifer match or of one or two candles, the vanes invariably turned the opposite way to the normal, the polished surface being repelled. With a dark heat, as from an iron shovel heated short of redness, they went the normal way. These effects continued for several days, but not permanently; the apparatus seemed to have leaked and to have become sluggish and irregular.

2. On electrising the protruding platinum wire with a rubbed rod of glass or sealing-wax, the vanes rotated sometimes one way and sometimes the other.

3. On connecting the negative pole of a Ruhmkorff's coil the results were uncertain, but the positive pole caused the vanes to rotate steadily, and its effect was even better than that from light or heat. In the dark the effect was very beautiful, as the dark vanes moved through a phosphorescent glow. The total results were considered by Sir William Grove to be somewhat negative, but they tended to show that all the effects were due to residual air. He suggested in explanation of the last experiment, that more electricity would escape from the rough than from the polished faces of the vanes, as the former presented a vast number of points. Consequently the rough faces would produce more disturbance of the gas in front of them, and would themselves be more affected by the reaction than the plane faces. The polished surfaces being repelled by luminous heat is, however, very difficult of explanation.

In his second notice Sir William Grove described some further experiments he had made with Crookes's radiometers since the last meeting of the club. He did not now entertain much doubt that these movements are due to the effect of residual air. Mr. Crookes had kindly made a second instrument for him, and the one that he described at the last meeting, of which the vanes were metallic and in metallic connection with a platinum wire that protruded outside the apparatus, had been re-exhausted. Both now act normally, the black faces of the vanes being repelled by light and by heat. When the protruding wire is now electrised by a Ruhmkorff's coil the effects that were previously observed are altogether absent, there is not the slightest luminosity round the vanes, and the current does not pass. But although the current is now incapable of traversing the

[2] Who kindly made it for me from my description.—W. R. G.

small space of one-tenth of an inch that separates the vanes from the glass, induction acts across it just as well as before. This is shown by the readiness with which the vanes follow the movements of a piece of rubbed glass or sealing-wax held near the apparatus. It is therefore evident that the effects of attenuation of air upon discharge and upon induction are not the same. When attenuation has commenced and is increasing, the discharge passes more and more rapidly, until it becomes a glow, or according to the old theory of electricity, polarisation becomes more and more readily subverted; but a further attenuation stops the discharge entirely. On the other hand, induction continues, and appears to be in no way lessened by extreme attenuation. These results cannot be accounted for by the old theory that discharge is the consequence of subverted induction.

It farther appears that a radiometer is a most delicate electroscope. By tilting it until the vanes touch the glass, the interior of the glass may be electrised, and it will then remain for days in that condition. He had performed this operation eight days ago, and the movements of the instrument by light or heat have been thereby wholly checked. Every endeavour has been made to discharge or neutralise the electricity on the glass surface, as, for example, by covering the exterior of the globe with tinfoil and connecting this with the platinum wire, nevertheless the glass remains charged, showing what a perfect insulator a good vacuum is.[1]

RESEARCHES ON THE RADIOMETER.

By Prof. Paul Volpicelli.

1. All radiometers do not possess the same sensibility necessary for every experiment.

2. The most sensitive of the two which are in the physical museum of the Roman University shows that the freezing mixture of chloride of sodium and snow, applied to the upper hemisphere of the small globe, produces a rotation of the mill in the same direction in which it is produced by heat radiation, *i.e.*, with the white face of the small discs in advance.

3. If to this lowering of temperature be added a radiation of heat, the rotation of the apparatus is accelerated at the same time.

4. If the freezing mixture referred to be placed on the lower hemisphere of the same small globe, the apparatus will rotate with the absorbing, *i.e.*, the black faces in advance, and consequently in the direction contrary to that of the preceding experiment, *i.e.*, to the direction produced, if to the same lower hemisphere radiant heat be applied.

5. If during the rotation produced by the application of the freezing mixture to the lower hemisphere of the small globe we cause radiant heat to strike the same globe, the apparatus will be brought to a stop; and, as soon as the source of heat is withdrawn, the rotation will immediately recommence.

6. If the small globe is plunged entirely in a heated liquid, or even in a freezing mixture, the apparatus will remain at rest.

7. It should be noted that the freezing mixture applied to the upper hemisphere of the small globe produces a rotation in the direction opposite to that produced by the same mixture when applied to the lower hemisphere.

8. It has been stated that the radiometer in darkness remains at rest; but it should be remarked that if even in darkness it is affected by dark radiant heat, the apparatus will assume a rotatory movement; yet the instrument may remain at rest even when placed in a dark space.

9. The luminous rays of the full moon, focussed by means of a lens, do not cause rotation of the instrument.

10. If the radiation of the flame of a Locatelli lamp is caused to traverse several plates of perfectly transparent glass, it will be seen by the number of turns of the instrument that the law of De la Roche is verified regarding the absorption of radiant heat through these plates, however many they may be. I have been able by this means to diminish the radiant heat to such an extent as to cause the rotation of the radiometer to cease, although the light of the same radiation was increased by means of a lens.

11. The same radiation, that, viz., produced by Locatelli's lamp, by traversing a saturated but perfectly transparent solution of alum, before reaching the radiometer, did not set it in motion, although the radiant light was but little diminished; and the same is the case when the light is increased.

12. It would appear at present that the rotation of the radiometer depends on radiant heat and not on the luminous rays.

13. It appears also that the mechanical cause of the rotation of the radiometer consists in the motion of the molecules of very rarefied gas in the small globe, which is in accordance with the opinion of modern thermodynamics.—*Nature.*

RADIOMETER.

[12358.]—An interesting discussion took place in the pages of the English Mechanic a short time ago upon the radiometer, and various conjectures were hazarded as to whether the rotary movement of the vanes was caused by heat, electricity, or the expansion of the residual air contained in the bulb of the radiometer, or so-called vacuum. There is apparently a difficulty in forming a perfect vacuum. Would it not be possible to construct a radiometer with a vacuum equal to that in a good barometer? Suppose a glass tube, say of the same bore as a barometer tube, but widening at the top to, say, 2½ or 3in. in diameter, fitted with an air-tight screw-on brass cap, would it not be an easy matter to fit in the broad part of the tube a roll of fine silk covered with wire, the ends of which might project through the bulb? The vanes, which appear to be made of iron, might be pivoted in the same way as vertical galvanometer needles, on a fine point. Now screw off the cap, put on the vanes, stop up the lower end of the rod with the finger, fill the tube, screw on cap, invert rod, and drive out with heat what air there may be in the mercury, and invert in a vessel of mercury. Should the vanes be liable to fall off during the operation a current of electricity through the coil would prevent them, the mercury would be allowed slowly to fall until at the same height as that in a barometer; the bulb would then be a perfect vacuum.

Jean.

RECENT RADIOMETER EXPERIMENTS.

At a recent meeting of the Physical Society, London, Professor G. C. Foster, F.R.S., President, in the chair, Mr. Crookes described some of the most recent results he has obtained in his experiments on the radiometer, and exhibited many beautiful forms of the apparatus, most of which have been devised with a view to decide on the correct theory of the instrument. He commenced by describing the arrangement he has used for some time past in studying the resistance offered by air and other gases to the rotation of a mica disk. It consists of a mica plate suspended by a fibre of glass, and enclosed in a chamber which can be exhausted to any required extent. A mirror is attached to the mica, and the movement of a luminous point reflected from it shows that the decreasing swings form a logarithmic curve, and Mr. Crookes takes the logarithms of the decrements of the swings as a measure of the viscosity of the gas under examination. From the normal atmospheric pressure to the best vacuum which can be obtained by the ordinary air-pump this decrement remains nearly constant, and these experiments have been carried on in vacua of remarkable perfectness, the highest exhaustion obtained being represented by 1 millimetre on a scale of 10 miles, a point which was attained by means of a Sprengel pump, with improvements by Mr. Gimingham, and measured by a McLeod gauge. If the "logarithmic decrement" be represented by 125 at a pressure of 760 m.m., it is not reduced to 70 until the pressure has been reduced to 35 millionths of an atmosphere, and at this point the action of light on a radiometer is at a maximum. On continuing the exhaustion this influence is found to decrease, and Mr. Crookes concludes that in a perfect vacuum the log. dec. would not be zero, but about 0·01; that is, a mica plate would not continue to oscillate forever, a fact probably due to the viscosity of the glass fibre. About fifteen different forms of the radiometer were exhibited, and their inventor has satisfied himself that the theory of their action proposed by Mr. G. Johnstone Stoney is the only one capable of completely accounting for their action, and he considers it to be in all probability the correct one. By means of a double radiometer, consisting of two globes of different diameters, and having a wide opening between them, and provided with a four-armed fly which can be made to rotate in either bulb, it has been shown that, other things being equal, the velocity of rotation decreases as we increase the diameter of the bulb. As, on the molecular-movement theory, the rotation is due to a throwing off of particles from the blackened surface of the mica, it follows that, if a piece of transparent mica be attached to exactly in front of the blackened surface, the rotation will take place in the opposite direction, and this proved an experiment to be the case. And, further, when such a plate is placed on either side of the vanes, the motion of the instrument is almost entirely stopped. As these facts can be explained on the "molecular movement" or the "evaporation and condensation" theory, Mr. Crookes arranged a radiometer having four transparent mica vanes, and mounted in a rather large bulb. At the side of the bulb a plate of mica, blackened on one side, is so fixed in a vertical plane that the vanes can pass, and when light shines on this fixed plate the fly is found to rotate, a fact which in itself disproves the latter theory. Many other curious forms were exhibited, in some of which the vanes were cup-shaped, as Mr. Crookes has found these to act as well as the ordinary form, a convex surface acting as though it were blackened. In conclusion, he exhibited a photometric four-vaned radio-

meter, in which the fly was attached to a small magnetic needle, and this might be so checked by an external magnet that the strongest light would be incapable of causing the needle and vanes to make a half rotation. If the circumference of the globe be graduated, and the apparatus be brought within the influence of a source of light, the angle to which the needle is deflected will be a direct measure of the intensity of the light, and Mr. Crookes shewed that by a simple arrangement such an instrument might be rendered self-recording.

Prof. Dewar exhibited a simple electrometer which he has designed, founded on the discovery of Lippmann that the capillary constant is not really independent of the temperature or the condition of the surface, but is a function of the electromotive force. If a capillary tube be immersed in mercury, and dilute sulphuric acid be placed in the tube above the mercury, and a current from a Daniel's cell be so passed through the liquids that the mercury forms the negative pole, the column will be depressed to an extent dependent on the diameter of the tube. In making an electrometer Prof. Dewar has increased the sensitiveness by connecting two vessels of mercury by means of a horizontal glass tube filled with the metal, except that it contains a bubble of dilute acid. The tube must have an internal diameter of 2 millimetres, and it is essential that it be perfectly clean, uniform in diameter, and horizontal. The instruments exhibited were constructed by Messrs. Tisley & Spiller, and Prof. Dewar showed that it is possible by means of them to measure an electromotive force equal to [illegible]th of a Daniel's cell; forces capable of decomposing water must be measured by causing two currents to act against each other. The index bubble is brought to zero by uniting the mercury cups by a wire. The apparatus is very convenient, as it requires no preparation, and is extremely simple in its action. He then showed an instrument, arranged by Mr. Tisley, for producing a current by the dropping of mercury from a small orifice into dilute sulphuric acid. If the vessels containing the mercury and the sulphuric acid be connected by a wire a current is found to traverse it, and Prof. Dewar explained how the electrolysis of water might be effected by this means. He then exhibited a delicate manometer suitable for measuring very slight variations of pressure, and he illustrated the use of it for proving Laplace's law that the internal pressure, multiplied by the diameter of a soap-bubble, is constant. It consists of a U-tube, one arm of which is about 15 inches long, and is bent horizontally, and levelled with great care. If the shorter arm be connected with a tube on which a bubble has been blown, and the diameter of the bubble be varied, the position of the extremity of the alcohol column will be found to vary in accordance with the above law.

Crookes' Force.—During the last twelve months Mr. G. T. Stoney, F.R.S., and Mr. R. J. Moss have conjointly been investigating the behaviour of that force in radiometers known as Crookes' force, and they have laid before the Royal Society some of the results so far obtained. If, as has been asserted, the pressure which is exerted on the blackened-pith surfaces reacts on the side of the glass envelope, then in like way a transparent disc, delicately suspended close to a stationary disc of blackened pith, ought to move away from the pith, and, therefore, towards the light when the pith is illuminated. An arrangement, described in their paper, was devised to test this. As soon as the vacuum commenced to be formed, the glass disc was repelled from the pith, and the repulsion was more violent as the vacuum became more perfect. The establishment of this fact with regard to this mysterious force the authors put forward without any expression of doubt. With regard to the influence of variations in the tension of the residual gas, and the variations in distance between the reacting surfaces, the authors state some results, but reserve discussion till further observations have been made.

38

PHYSICAL SOCIETY.

From the Telegraphic Journal.

At the meeting of the Physical Society on Jan. 16th Mr. Crookes described some of the most recent results he has obtained in his experiments on the radiometer, and exhibited many beautiful forms of the apparatus, most of which have been devised with a view to decide on the correct theory of the instrument. He commenced by describing the arrangement he has used for some time past in studying the resistance offered by air and other gases to the rotation of a mica disc. From the pressure to the best vacuum which can be obtained by the ordinary air-pump the resistance remains nearly constant, and the experiments have been carried on in vacua of remarkable perfectness, the highest exhaustion obtained being represented by one millimetre on a scale of ten miles, a point which was attained by means of a Sprengel pump with improvements by Mr. Gimingham, and measured by a McLeod gauge. Mr. Crookes concludes that in a perfect vacuum a mica plate would not continue to oscillate for ever, a fact probably due to the viscosity of the glass fibre employed. About 15 different forms of the radiometer were exhibited, and their inventor has satisfied himself that the theory of their action proposed by Mr. G. Johnstone Stoney is the only one capable of completely accounting for their action, and he considers it to be in all probability the correct one. As, on the molecular movement theory, the rotation is due to a throwing off of particles from the blackened surface of the mica, it follows that, if a piece of transparent mica be attached to each fly in front of the blackened surface, the rotation will take place in the opposite direction, and this proved on experiment to be the case. As these facts can be explained on the "molecular movement" or the "evaporation and condensation" theory, Mr. Crookes arranged a radiometer having four transparent mica vanes, and mounted in a rather large bulb. At the side of the bulb in a vertical plane, a plate of mica, blackened on one side, is so fixed that the vanes can pass, and when light shines on this fixed plate, the fly is found to rotate, a fact which in itself disproves the latter theory. In conclusion, he exhibited a photometric four-vaned radiometer, in which the fly was attached to a small magnetic needle, and this might be so checked by an external magnet, that the strongest light would be incapable of causing the needle and vanes to make a half rotation. If the circumference of the globe be graduated and the apparatus be brought within the influence of a source of light, the angle to which the needle is deflected will be a direct measure of the intensity of the light.

Radiometer.—A comparison has recently been made by Dr. Buff between the indications of the thermomultiplier and the radiometer. The two instruments were placed side by side in the cone of light admitted through an aperture of a hood from a gas lamp, which could easily be regulated and kept constant for some minutes. There was a glass disk in front of the thermopile. In the galvanometer deflections of the needle were proportional to the deflecting force up to 21°. On tabulating deflections and numbers of rotations, it appears that their product is very nearly a constant number, warranting the inference that *the velocity of rotation of the little wheel is inversely proportional to the heat action of the penetrating rays.* This confirms the view that the turning of the radiometer is due to an action of heat rays which penetrate the glass. "If the radiometer," says Dr. Buff, "is incapable of measuring a mechanical force of light, it none the less wears its present name with full right. It is a special form of thermometer, only exclusively for heat rays of high refrangibility, whose heating force is proportional to the velocity of rotation of the wheel."

PHYSICAL SOCIETY.

Professor G. C. Foster, F.R.S., President in the chair.

Stratification of the Electric Discharge in Vacuum Tubes.—Mr. Spottiswoode exhibited some experiments and described his attempts to produce the effects as obtained by Mr. Gassiot and Mr. De la Rue, with batteries of several thousand cells by means of the induction coil. He showed the different forms of striæ produced in several different gases, and mentioned that the side towards the negative is always sharply defined, and that towards the positive gradually shades off into darkness. Mr. Spottiswoode has examined them by means of a rotating mirror, the mercury break being worked by the axis of the mirror so that the one only varies with the other. It was thus clearly ascertainable whether a band was progressing towards either pole or remaining stationary, or was intermittent, according as the line observed in the mirror was inclined or horizontal or broken. He considers that the ordinary break prolongs the sparks, so as, in some cases, to give rise to the ill-defined nature of the striæ, and he showed two forms of contact breaker adapted to these experiments. In the first the breaking was effected by a steel rod caused to vibrate by an electro-magnet, the number of these vibrations being determined by the musical note produced. In the apparatus now usually employed, however, a brass wheel is caused to rotate with great rapidity, the tops of the teeth are covered with platinum, the spaces between them being filled in with ebony. It was shown that if the current be made and broken by a wire resting on the rim of this wheel, the bands may be caused to move in one direction or the other, or remain stationary, according to the velocity of rotation of the wheel. A very ingenious arrangement, invented by Mr. Spottiswoode's assistant, Mr. Ward, was employed for introducing resistance into the secondary circuit, and thereby adjusting the strength of the current to suit the velocity of rotation of the wheel. It consisted of a spiral column of mercury surmounted by a vessel containing a badly conducting liquid, and by raising or lowering a cup connected with the base by means of an india-rubber tube, the amount of mercury present in the column is increased or decreased, the resistance offered by the column of constant length of course varying in the inverse proportion

it had flowered profusely, I could not find a single normal fruit, and subterranean ones were extremely scarce.

According to Delpino the changing colours of certain flowers would serve to show to the visiting insects the proper moment for effecting the fertilisation of these flowers. We have here a Lantana the flowers of which last three days, being yellow on the first, orange on the second, purple on the third day. This plant is visited by various butterflies. As far as I have seen the purple flowers are never touched. Some species inserted their proboscis both into yellow and into orange flowers (*Danais erippus*, *Pieris aripa*), others, as far as I have hitherto observed, exclusively into the yellow flowers of the first day (*Heliconius apseudes*, *Colaenis julia*, *Eueides lineata*). This is, I think, a rather interesting case. If the flowers fell off at the end of the first day the inflorescence would be much less conspicuous; if they did not change their colour much time would be lost by the butterflies inserting their proboscis in already fertilised flowers.

In another Lantana the flowers have the colour of lilac, the entrance of the tube is yellow surrounded by a white circle; there yellow and white markings disappear on the second day.

Mr. Leggett's statements about *Pontederia cordata* appear to me rather strange, and I fear that there is some mistake. In all the five species of the family which I know the flowers are so short-lived, lasting only one day, that a change in the length of the style is not very probable. In the long-styled form of our high-and Pontederia the style has its full length long before the flowers open. In my garden this Pontederia is visited by some species of Augochlora collecting the pollen of the longest and mid-length stamens; they are too large to enter the tube of the corolla, and have too short a proboscis to reach the honey; they can only fertilise the long-styled and mid-styled forms, but not the short-styled.

Among the secondary sexual characters of insects the meaning of which is not understood, you mention ("Descent of Man," vol. i., p. 345) the different neuration in the wings of the two sexes of some butterflies. In all the cases which I know this difference in neuration is connected with, and probably caused by, the development in the males of spots of peculiarly-formed scales, pencils, or other contrivances which exhale odours, agreeable no doubt to their females. This is the case in the genera Mechanitis, Dircenna, in some species of Thecla, &c.

FRITZ MÜLLER

Blumenau, St. Catharina, Brazil, October 19

The Radiometer and its Lessons

PROF. OSBORNE REYNOLDS's letter in NATURE (vol. xvi. p. 26) has directed attention prominently to the circumstance that two hypotheses have been submitted to the scientific world as explanations of the force and motions which Mr. Crookes had shown to exist—one by Prof. Osborne Reynolds, the other by myself.

Prof. Osborne Reynolds's explanation is based on the fact that when a disc with vertical sides is heated on one side and exposed to a gas, a convection current sets in, which draws a continuous supply of cold gas into contact with the hot surface of the disc. As this cold gas reaches the disc it is expanded, and thus its centre of gravity is thrown farther from the disc. Accordingly, the disc, if freely suspended, will move in the opposite direction so as to keep the centre of gravity of the gas and disc in the same vertical line as before, and, if not freely suspended, will suffer a pressure tending to make it move in that direction. If I have understood Prof. Reynolds aright, this is both a correct and full description of his explanation as last presented.

My explanation, on the other hand, is based on *molecular* motions which go on in the gas without causing any molar motion, and is independent of convection currents. Prof. Reynolds is therefore, I conceive, fully justified in denying that my theory has supplied any deficiency in his explanation. As he points out, the two explanations are incompatible; if either is correct, the other is wholly wrong.

It is easy to apply comparative tests to the rival hypotheses by making a selection from Mr. Crookes's incomparable experiments, from the experiments by Mr. Moss and myself, and from instances of compressed Crookes's layers in the open atmosphere; but it is not easy to make the choice so as to bring the abundant evidence within the compass of a letter.

These tests might take various forms, of which perhaps the most direct is to ascertain whether the force is affected by variations in the convection current, as required by Prof. Reynolds's hypothesis, or is independent of convection, but increased when the heater and cooler are brought nearer together, as required by mine.

To test this Mr. Crookes mounted a radiometer in a receiver consisting of two unequal bulbs connected by a large tube. The movable portion could be transferred from one bulb to the other through the tube. In the small bulb the convection current is most impeded, and at the same time the heater and cooler are closest together. Mr. Crookes found that the motion of the radiometer was more rapid in the small bulb than in the large one, in conformity with my theory, and in opposition to Prof. Reynolds's. The same is the uniform drift of a vast number of other experiments by Mr. Crookes, and of those by Mr. Moss and myself, from which it appears that whenever the heater and cooler are made to approach there is an increase in the force, and that the force is not appreciably affected by variations of the convection current, or by its suppression.

This may also be proved, and quite conclusively, by observations not requiring apparatus. Drops in the spheroidal state and the drops which are often seen floating on the surface of volatile liquids, as, for example, the drops which run about on the surface of the sea in certain states of the weather when water drips from an oar, are supported by Crookes's layers of air intervening between them and the liquid beneath. Similarly a red-hot copper plate will float on water, supported on a Crookes's layer, and many other instances of a like kind might be adduced. In such cases, where the film of air is thin and for the most part horizontal, it is manifest that there is no opportunity for those convection currents to arise which are required by Prof. Reynolds's hypothesis, while in all of them there are the peculiar molecular motions of my theory.

The absence of convection currents which could produce an appreciable effect may also be proved in those radiometers of which the arms whirl round at a very rapid speed, and in many other cases that would take too much space to describe here.

Again, a tangential force which may be rendered considerable is an immediate consequence of my theory, but has no place as a consequence of Prof. Reynolds's. Now its presence has been verified by Mr. Moss and myself, and by Mr. Crookes in an exquisitely beautiful apparatus suggested for this purpose by Prof. Stokes, as well as, in a less degree, in all Mr. Crookes's apparatus with curved or crumpled discs.

Hence Prof. Osborne Reynolds's hypothesis is not the explanation of Crookes's stress. It alleges a cause which is in certain cases a *vera causa*, but not *the* cause of what is to be explained. So far as I can form a judgment, its merit was collateral, and not intrinsic. It was the first attempt at a reduction of the observed phenomena to known physical laws. Though not accounting for them, it was sufficiently plausible to attract the attention of Prof. Reynolds and other physicists. It thereby had the important effect of suggesting Dr. Schuster's most valuable experiment, which was the first that established the cardinal fact that the forces within a radiometer case are balanced.

The conclusion to which we are thus led by a purely *experimental* inquiry is supported by an examination of the chief *theoretic* assertions of Prof. Osborne Reynolds's letter, viz., 1. That an essential part of my explanation "is contrary to the law of the diffusion of heat in gases;" and 2. "That the force arising from the communication of heat from a surface to adjacent gas of any particular kind depends only on one thing, the rate at which heat is communicated, and to this it is proportional."

Both of these statements have been set down by Prof. Osborne Reynolds in error; the first from not observing that the ordinary laws for the propagation of heat through a gas do not apply to compressed Crookes's layers; and the second from a misapprehension of the actual agency at work in radiometers and other similar apparatus. I will proceed to establish these two positions.

1. So long as a gas is in its ordinary state the distribution of the velocities of the molecules is the same in all directions, and when heat is imparted to the gas it does not disturb this uniformity of structure. The heat simply increases the mean velocity, and the actual velocities continue to be distributed about

CAREY FOSTER

EXPERIMENTS WITH THE RADIOMETER

I.

ABSTRACTS of my earlier papers on "Repulsion Resulting from Radiation" having appeared in NATURE, it has been suggested that an account of my later researches, which place the subject in such a different light, may also prove of interest.

It has already been shown that if the air is expelled from a large bulb containing a suspended bar of pith, and a lighted candle is placed about 2 inches from the globe, the pith bar commences to oscillate to and fro, the swing gradually increasing in amplitude until the dead centre is passed over, when several complete revolutions are made. The torsion of the suspended fibre now offers resistance to the revolutions, and the bar commences to turn in the opposite direction. It has been found, however, that very little movement takes place until the vacuum is so good as to be almost beyond the powers of an ordinary air-pump to produce, and that, as the vacuum gets more nearly absolute, so the force increases in power. The most obvious explanation therefore is, that the repulsive action is due to radiation; but at a very early stage of my investigation I found that the best vacuum I had succeeded in producing might contain enough matter to offer resistance to motion, and in describing an experiment in a paper sent to the Royal Society on February 5, 1876, I said that the impression conveyed to my mind was that the torsion beam was swinging in a viscous fluid, and the repulsion caused by radiation was indirectly due to a difference of thermometric heat between the black and white surfaces of the moving body, and that it might be due to a secondary action on the residual gas.

I have recently succeeded in producing such a complete exhaustion that I have not only reached the point of maximum effect, but gone so far beyond it that repulsion nearly ceases, and the results I have thus obtained seem to show conclusively that the true explanation of the action of the radiometer is that given by Mr. Johnstone Stoney, according to which the repulsion is due to the internal movements of the molecules of the residual gas. When the mean length of path between successive collisions of the molecules is small compared with the dimensions of the vessel, the molecules, rebounding from the heated surface, and therefore moving with an extra velocity, help to keep back the more slowly moving molecules which are advancing towards the heated surface; it thus happens that though the individual kicks against the heated surface are increased in strength in consequence of the heating, yet the number of molecules struck is diminished in the same proportion, so that there is equilibrium on the two sides of the discs, even though the temperature of the faces are unequal. But when the exhaustion is carried to so high a point that the molecules are sufficiently few, and the mean length of path between their successive collisions is comparable with the dimensions of the vessel, the swiftly-moving, rebounding molecules spend their forces in part or in whole on the sides of the vessel; and the onward crowding, more slowly-moving molecules are not kept back as before, so that the number which strike the warmer face approaches to, and in the limit equals, the number which strike the back cooler face; and as the individual impacts are stronger on the warmer than on the cooler face, pressure is produced, causing the warmer face to retreat.

Before referring at length to the experiments which led to my adopting the above theory, I will describe some effects of dark heat, &c., on the radiometer. In a paper I sent to the Royal Society on January 5, 1876, and which is now being published in the *Philosophical Transactions* of the Royal Society, about seventeen pages are occupied with the description of my experiments with various forms of this instrument. In the present paper I propose only to refer to a few typical experiments made during the year 1875.

To show the action of dark heat on the radiometer, a candle was placed at such a distance from the instrument that the arms would make one revolution a minute. A small glass flask of boiling water was then placed half-an-inch from the bulb. The revolutions instantly stopped, two of the arms setting equidistant from the hot-water flask. The flask of water was removed. As the portion of the bulb which had been heated by the hot water cooled, the white surface gradually crept nearer and nearer to it, the superior repulsion of the candle on the black discs urging the arms round, and acting in opposition to the repulsion of the hot glass to the white disc. At last the force of the light drove the white disc with difficulty past the hot spot of glass. Rotation then commenced, but for some revolutions there appeared to be a difficulty in the white discs passing the spot of glass which had been warmed by the hot water; and the flask of boiling water being replaced in its position half-an-inch from the bulb of the radiometer, the rotation immediately stopped.

The instrument having become cool, the candle was again placed in position, so that it produced one revolution in a minute. The finger was then pressed against the side of the bulb, and as the spot of glass got warm, the white surface experienced more and more difficulty in getting past it, until at last one refused to pass, and the arms came to rest.

The instrument was again allowed to cool, and the revolutions recommenced at the usual speed (the laboratory in which this was tried was somewhat cold). I then came from a warm room, and stood a foot from the radiometer, watching it. In about a minute the radiant heat from my body had warmed the side of the bulb nearest to me sufficiently to cause an appreciable difficulty in the movement, and soon the revolutions stopped. The same effect has been observed if the radiometer is brought into a very warm room and placed near a cold window. If the daylight is feeble, the instrument not very sensitive, or an observer stands near the instrument, an appreciable sticking is observed as the white discs come near that part of the bulb which is the warmest.

These experiments show that many precautions are necessary to guard against the interfering action of unequal heating of the radiometer when it is being used for accurate measurements.

Having found such an antagonistic action of dark heat, I tried the action of ice. This is equivalent to warming the opposite side of the instrument. A lump of ice was brought within half an inch of the bulb on the opposite side to the candle. The revolutions got slower, until at last the movement stopped altogether, one arm pointing direct to the ice, and being apparently held there by a powerful attractive force. Bringing the candle nearer caused the arms to oscillate a little, and when it was almost close to the bulb the force of the light overcame the action of the ice, and the arms revolved again, but irregularly, and with jerks, the discs moving quickly to the ice and leaving it with difficulty. In this action of ice no preference was noticed for either the black or white surface.

A very delicate radiometer, in 2-inch bulb, was placed in a sufficient light to allow it to be seen distinctly, but not enough to cause it to move. I then came out of a warm room and stood near it. In a few seconds it began to move slowly round in the negative direction, *i.e.* the black discs advanced instead of retreated. On moving away from the instrument the rotation gradually stopped. I again approached it, and held one hand an inch from the bulb. Rotation soon commenced, but still in the reverse way. These experiments were frequently repeated and always with the same results.

When the instrument was at rest I came quickly to it, and gently breathed on the bulb. There was a slight movement in the normal direction, but this stopped directly, and the arms then revolved the reverse way for more than a minute, performing three or four complete revolutions.

A glass shade four inches in diameter was held over a gas-flame till the air inside was warm, and the inner surface dim with steam. It was then inverted over the radiometer. Rotation commenced the reverse way, and kept up for several minutes. The glass shade was then dried inside, and heated uniformly before a fire until it had a temperature of about 50° C. It was then inverted over the radiometer. Reverse rotation instantly commenced, and kept up with some vigour for more than five minutes, diminishing in speed until the shade had cooled down to the temperature of the surrounding air.

The same experiment was repeated, and whilst the arms were in full negative rotation, a lighted candle was slowly brought near it. When three feet off the negative rotation slackened. When the candle was about two feet off the arms became still, and when nearer than two feet the instrument rotated normally, the antagonism between the action of the hot shade and the lighted candle was perfect; by moving the candle to and fro it was easy to cause the radiometer to move in one direction or the other, or to become still.

I now tried the action of a radiometer the moving parts of which were made of a good conductor of heat, such as a metal, instead of pith, which is a bad conductor of heat. I selected thin rolled brass as the material wherewith to make the arms and discs of a radiometer. The parts were all fastened together with hard solder, and no cement or organic matter was used, so that if necessary the instrument could be submitted to a high temperature without injury. The moving portion weighed 13·1 grains. One side of the discs was silvered and polished, the other side being coated with lampblack. The apparatus was exhausted with a charcoal reservoir attached. A candle 1½ inch from the bulb caused it to revolve about once a second, the black surface being repelled in the normal manner.

Standing in a rather dark cold room, it was covered with a warm glass shade, and it immediately began to revolve the negative way, but very slowly. A few drops of ether poured on the bulb caused the arms to move rather rapidly the normal way. A hot shade put over whilst it was thus moving caused it to stop and then begin moving the reverse way. A small non-luminous gas flame was held vertically beneath the apparatus, so that hot air should ascend and wrap round the bulb on all sides. The arms now revolved the reverse way.

The brass radiometer being somewhat heavy, one was made of aluminium, the moving parts being hard soldered as before. A siphon-gauge was attached, and the apparatus connected direct on to the pump by a spiral, no charcoal tube being used. One side of the wings was bright aluminium, and the other was lampblacked. When exhausted the arms revolved very quickly to a candle a few inches off, the black being repelled. On removing the candle the arms stopped and immediately commenced revolving the reverse way, keeping up rotation for more than ten minutes, and being little inferior in speed to what it was when the candle shone on it. The whole of the bulb was heated with a Bunsen burner; whilst it was getting hot the aluminium arms revolved rapidly in the normal direction, but as soon as the source of heat was removed and cooling commenced, rotation set up in the reverse way, and continued with great energy till the whole thing was cold. It appeared as if the reverse movement during the cooling was equal in energy to the normal movement as it was being heated.

A little ether was poured on the bulb of a very sensitive pith radiometer as it was standing still in a faint light. The evaporation of the ether caused a chilling of the instrument and a rapid abstraction of heat from the arms. They commenced to move in the normal direction and

ON REPULSION RESULTING FROM RADIATION.—PART IV.*

By WILLIAM CROOKES, F.R.S., &c.

(Concluded from p. 56.)

The Measurement of Force.

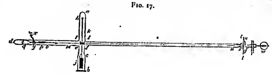
209. I have long endeavoured to devise some means of measuring the amount of force exerted by radiation, from a standard candle for instance at a foot off, on a measured surface of matter. The data given in pars. 199 and 200 are sufficient to enable the amount of force acting on the pith disks to be calculated indirectly; but I wished to have a means of measuring the force by as direct a method as we have of getting the weight of a ponderable body. I wanted an apparatus which will give me, at once, the pressure in grains which a ray of light exerts on a surface on which it may fall. Such an apparatus is shown in fig. 17.

The principle of the construction is that of the torsion-balance first described by W. Ritchie, F.R.S., in 1830.† *a b* is a glass tube 13·5 inches long, 1 inch wide as far as *a c*, and 1·2 inch wide at *c b*. It is closed at the end *a*, and ground flat and polished at the end *b*, so as to be capable of being closed by a plate of glass cemented on. *d e* and *f g* are two narrower tubes sealed into *a b*, as shown, the part *d e* being 17 inches long, and *f g* 38 inches long. *d e* is ½ an inch in diameter, and is closed at the end; *f g* is a ¼ of an inch diameter. *h i* is a thin glass beam, having a glass weight at the end *h*, and a flat surface of lampblacked pith (*j*) at the end *i*. The pith (*j*) exposes exactly 2 square inches of surface. It is prevented from curling up in the vacuum by cutting it partly through at intervals, as shown. *k* is a silvered mirror, cemented on to the centre of the glass beam; *l l* are two knife-edges of glass, finely ground and polished; *m n* is a very fine fibre of glass cemented to the beam (*h i*) beneath the mirror (*k*). The end (*n*) of the glass torsion-fibre is attached to the solid stopper (*r*), which is carefully ground and polished into the contracted part of the tube (*s*). The other end of the torsion-fibre (*m*) is cemented to a filament of silk (*m o*); this silk is attached to one end of a steel spring (*p*), which is held firmly at the other end by the solid rod (*q*) cemented to the glass tube (*d e*). The torsion-fibre (*m n*) passes over the knife-edges (*l l*), which thus support the beam. The tension of the spring (*p*) is so adjusted that the glass fibre shall remain stretched under a constant pull of about 100 grains. *t t* is a circular card cemented to the end of the tube (*e*) and divided into 360 degrees. On the stopper (*r*) is fixed a pointer (*u*), which revolves with it, and marks the degrees through which it has turned. The complete revolutions are recorded on a "counter" (*w*). Motion is given to *r* by a torsion-handle (*v*). The apparatus is connected to the pump by the spiral (*x*), which works in a stopper tap (*y*) most ingeniously devised by my friend and assistant Mr. C. H. Gimingham, so as to enable the instrument to be disconnected from the pump and attached to it again without interfering with the exhaustion.*

The stopper (*r*) is very accurately ground and polished in the tube at *s*, as long a surface as possible being in contact. It should be lubricated by setting fire to a piece of plain india-rubber, and allowing the melted drops to fall on the contact surfaces. This is a nearly perfect lubricant, allowing very free movement and preventing any access of air.

210. The torsion-fibre must be selected with great care.

FIG. 17.



Plan.

Elevations and details.

Vertical section of cross tube at the centre.

Vertical section of cross tube at the end containing the pith.

Ten threads were drawn (193) and were suspended from a horizontal beam. Weights were then gradually hung on to the lower ends. Only two were found strong enough, the others having broken before 450 grains had been added. The one selected stood 450 grains without breaking. Its diameter is less than 0·001 inch.

The torsion of the glass fibre was taken by the method given in par. 186. With the weight of 15·46 grains hanging on to it half an oscillation took 30 seconds.

A fellow thread, selected of as nearly as possible the same strength and tension, and having a weight of about 100 grains at the end, broke when it was twisted 36 times. The actual thread used in the balance has been tested up to 30 turns without breaking.

211. A flat oblong piece of soft iron, weighing accurately one grain, is put loose into the cross tube under the pith surface (see *s*, fig. 17, vertical section of cross tube). This weight can be picked up by a horseshoe magnet outside the tube, and dropped on any part of the pith. A mark is made at the exact centre of the pith surface, and by moving the magnet about, it is easy to place the iron weight accurately on this mark.

212. A silvered glass mirror is supported at an angle of 45° over the pith surface, and so that the centre of the mirror is 2 inches from the pith when the beam is in

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

The Radiometer and its Lessons

HAVING been prevented from attending the recent meeting of the British Association by the necessity of devoting my entire vacation to mental and bodily renovation after the sad family losses I had sustained, I have only become aware within the last few days that my article in the April number of the *Nineteenth Century*, entitled "The Radiometer and its Lessons," had been there spoken of by Prof. G. Carey Foster, in his address as President of Section A, as showing an "unmistakable tendency, *either intentionally or unintentionally*, to depreciate Mr. Crookes's merits, and to make it appear that he had put a wrong interpretation upon his own results," which statement is said by your reporter to have "elicited great applause."

Of Mr. Crookes's own reply in the July number of the same periodical, entitled "More Lessons from the Radiometer," I took no notice; partly because my mind was at the time fully occupied by sad cares and urgent duties, and partly because I thought that his assertions (1) that he had not theorised on the subject at all, (2) that he had not attributed the rotation of the radiometer to the direct impetus of light, and (3) that he had never claimed the discovery of a new force or a new mode of force, were so well known in the scientific world to be inconsistent with fact, that I need not trouble myself to refute them.

Prof. Carey Foster, however, speaking with authority as President of the Physical section of the British Association, has given it as his judicial opinion that what I have written on this subject shows an unmistakable tendency to depreciate Mr. Crookes's merits, and to misrepresent his opinions; and he has further "unmistakably" suggested (as it appears to me) that this *may* have been done with deliberate intention, instead of being done in good faith under the influence of an unintentional bias. As it is impossible for me to allow such an imputation from such a quarter to pass unnoticed, I might fairly challenge Prof. Carey Foster to justify language which I must presume him to have used with all due consideration of its obvious meaning, and of *his* and *my* relative positions. But as he explicitly disavows the more serious part of this imputation, I have now only to ask to be allowed to show, in the columns of the journal which has not only recorded the accusation, but has pointedly directed attention to it,—*first*, that I have not, *even unintentionally*, "depreciated Mr. Crookes's merits" as the inventor of the Radiometer; and *secondly*, that Mr. Crookes really did in the first instance put that "wrong interpretation upon his own results" which I attributed to him. Had Prof. Carey Foster complied with the request I privately made him, that he should specify the passages which (in his opinion) justify his charge, I should have been able to reply to it much more briefly. But by declining thus to particularise, he obliges me to traverse the whole ground covered by his general accusation.

That I was not influenced, when writing on the Radiometer, by any *animus* arising from my personal antagonism to Mr. Crookes on another subject, will appear, I think, from the following extracts from the two lectures which I delivered at the London Institution (by special request) on Mesmerism, Spiritualism, &c., before Christmas, and which were published in *Fraser's Magazine* at the commencement of the present year:—

"The recent history of Mr. Crookes's most admirable invention, the Radiometer, is pregnant with lessons on this point. When this was first exhibited to the admiring gaze of the large body of scientific men assembled at the *soirée* of the Royal Society, there was probably no one who was not ready to believe with its inventor that the driving-round of its vanes was effected by the direct mechanical aid of that mode of Radiant Force which we call Light; and the eminent Physicists in whose judgment the greatest confidence was placed, seemed to have no doubt that this mechanical agency was something outside Optics properly so called, and was, in fact, if not a new Force in nature, a new *modus operandi* of a force previously known under another form. There was here, then, a perfect readiness to admit a novelty

which seemed so unmistakably demonstrated, though transcending all previous experience. But after some little time the question was raised, whether the effect was not really due to an intermediate action of that *mode* of Radiant Force which we call *heat*, upon the attenuated vapour of which it was impossible entirely to get rid; and the result of a most careful and elaborate experimental inquiry, in which nature has been put to the question in every conceivable mode, has been to make it (I believe) almost if not quite certain, that the first view was incorrect, and that Heat is the real moving power, acting under peculiar conditions, but in no new mode."—*Lectures on Mesmerism and Spiritualism*, p. 8.

"I hold the warning given by the history of this inquiry, in regard to the duty of the scientific man to exhaust every possible mode of accounting for new and strange phenomena, before attributing it to any previously unknown agency, to be one of the most valuable lessons afforded by Mr. Crookes's discoveries.

"Now I maintain that it requires exactly the same kind of specially trained ability to elicit the truth in regard to the phenomena we are now considering, as has been exerted in the researches made by the instrumentality of the Spectroscope and the Radiometer. And I cannot but believe that if Mr. Crookes had been prepared by a special training in the bodily and mental constitution, abnormal as well as normal, of the Human instruments of the Spiritualistic inquiries, and had devoted to them the ability, skill, perseverance, and freedom from prepossession, which he has shown in his Physical Investigations, he would have arrived at conclusions more akin to those of the great body of scientific men whom I believe to share my own convictions on this subject."—*Op. cit.*, p. 70.

No one, I think, can fail to see that in speaking of Mr. Crookes's "most admirable invention," and in giving him the fullest credit for the "ability, skill, perseverance, and freedom from prepossession," with which he had carried on his investigations in regard to it, I eulogised him as warmly as if I had never come into collision with him. It must also be apparent to any reader of these lectures, that I did not impute to him any blame for having originally fallen into an error shared at the time by the "eminent Physicists in whose judgment the greatest confidence was placed;" and that my reason for bringing forwards the subject was to enforce the lesson, that "no new principle of action has any claim to scientific acceptance, save after an exhaustive inquiry as to the extent to which the phenomena can be accounted for, either certainly or probably, by agencies already known."

Circumstances to which I shall presently advert having made me feel it desirable that this "lesson" should be yet more fully and emphatically set forth, I applied myself to a careful re-perusal of Mr. Crookes's papers in the *Proceedings* of the Royal Society, with the most earnest desire to present a true history of the whole inquiry; and I availed myself of the opportunity kindly afforded me by the editor of the *Nineteenth Century*, to place before the public what I believed to be a fair statement of the case, with the lessons it conveyed.

Commencing with a description of the phenomena presented by the Radiometer when it was first exhibited by Mr. Crookes at the *soirée* of the Royal Society, I thus continued:—

"It is scarcely surprising, then, that a general impression should at once have prevailed that a capital discovery had been made—that of the *direct mechanical action of light*; which, though not indicating the existence of a new force in nature, showed that the most universally diffused of all forces, next to gravitation, has a *mode of action* which was previously not merely unknown, but altogether unsuspected. And this impression was not confined to those who had only a general acquaintance with Physical Optics; for it was shared by the greatest masters of that department of science, who had followed the course of the experimental researches on which Mr. Crookes had been for some time engaged, and of which this discovery was the culmination."—*Nineteenth Century*, April, 1877, p. 243.

I then went on to give, from Mr. Crookes's papers, a history of the investigations which had led him up to the Radiometer; and showed (p. 249) that at that stage of the inquiry, the argument for the *directness of radiant repulsion*, deducible from what was then supposed to be a fact—the increase of the rapidity of the rotation in proportion to the perfection of the vacuum—"seemed alike valid and cogent."

I next sketched the history of the opposite view originally propounded by Prof. Osborne Reynolds, supported by Dr. Schuster's experiment, and finally established by Mr. Crookes's own later researches, which have culminated in the doctrine of "heat reaction" now generally accepted. In reference to Mr. Crookes's own part in these subsequent inquiries, I say later on (p. 251), that "no sooner was adequate ground shown for calling in question his interpretation of the phenomena, and a *vera causa* found in an agency already known, than Mr. Crookes evinced the spirit of the true philosopher in varying his experiments in every conceivable mode, so as to test the validity of his original interpretation." And again in the next page I speak of his "carrying out this beautiful inquiry in a manner and spirit worthy of all admiration."—What higher praise *could* be given to a scientific investigator?

Having brought the history to its conclusion, I thus proceed:—

"Before adverting to the lessons which this remarkable history seems to me to convey, I would point out that this change of interpretation of the facts discovered by Mr. Crookes, does not in the least diminish either the interest of the facts themselves or the merit of his discovery. Nor is the value of his Radiometer in any degree lowered by the demonstration that it does not (as Mr. Crookes at first supposed) afford an absolute mechanical measure of radiant energy under any of its aspects. What (according to present views) it really does measure, is the amount of 'heat reaction' producible in gaseous atmospheres of different kinds and of different degrees of attenuation. And such a precise method of measurement appears more likely than any other mode of investigation, to furnish a test of that kinetic theory of gases, the recent development of which by Prof. Clerk-Maxwell is regarded by competent judges as constituting (if it should receive such verification) the most important advance ever made in molecular physics. Most deservedly, therefore, did Mr. Crookes receive from the Royal Society the award of one of its chief distinctions." (*Loc. cit.*, p. 251.)

To this I may add that I personally congratulated Mr. Crookes most cordially on that occasion, and expressed to him the deep interest with which I had followed his researches throughout. And though I had next to show that Mr. Crookes has another side to his mind, which makes Mr. Crookes the "spiritualist" almost a different person from Mr. Crookes the "physicist," I carefully guarded what I had to say on this point in the following words:—

"I would not be thought for one moment to disparage Mr. Crookes's merits as the inventor of the Radiometer, by now bringing into contrast with the admirable series of scientific investigations which led up to that invention, what I cannot but regard as his thoroughly unscientific course in relation to another doctrine of which he has put himself prominently forward as the champion."

I cannot but surmise that Prof. Carey Foster must have read my paper rather carelessly, and have applied to Mr. Crookes, the inventor of the Radiometer, the depreciatory remarks I felt called upon to make in regard to Mr. Crookes, the supporter of a system, a large proportion of which even Mr. D. D. Home has recently denounced as "a seething mass of folly and imposture."[1] If Prof. Carey Foster knew as much as I do of the mischief which *this* Mr. Crookes has done, especially in the United States, on the one hand to his own reputation and to that of British science,[2] and on the other to public morality, by the facility with which he has lent himself to the support of frauds as wicked as those by which fortune-tellers delude ignorant and credulous servant-girls, he would not wonder that I should feel called upon to show that the high scientific ability of Mr. Crookes, the Physicist, neither prevents him from believing in his own day-dreams, nor renders him a match for the cunning of the clever female cheats who play upon his Spiritualistic "prepossessions."

I now pass to the second part of my defence; and shall show that for "making it appear that Mr. Crookes had put a wrong interpretation upon his own results," I can adduce adequate justification from his own published statements.

Of the "repulsion accompanying radiation" shown in his early experiments by the swinging-round of the pith bar, Mr. Crookes said, in 1874 (*Phil. Mag.*, vol. xlviii., p. 94), "*My own impression is that it is directly due to the impact of the waves*

[1] See his "Lights and Shadows of Spiritualism," containing an unsparing exposure of its "delusions," its "absurdities," and its "trickeries."

[2] On the strength of a private letter from Mr. Crookes, which has been published (*in fac simile*) in the American newspapers, a certain Mrs. or Miss Eva Fay announced her "spiritualistic" performances as "endorsed by Prof. Crookes and other Fellows of the Royal Society." The particulars of this complete public exposure of this woman's disgraceful frauds, showing that Mr. Crookes's *scientific tests* are no more worthy of trust than the late Prof. Hare's *experimental demonstration of the immortality of the soul*, will appear in the forthcoming number of *Fraser's Magazine*.

46

The Radiometer and its Lessons

As I now learn for the first time what are the grounds on which Prof G. C. Foster based his inculpation of me, I may ask for a *very* few last words. I fully admit that in giving a sketch of the history of the Radiometer, I *intended* to attribute to Mr. Crookes that he had in the first instance put a wrong interpretation upon his own results; because I believed that this was a simple fact, well known to everybody who had followed the history of the inquiry. And Prof. Carey Foster has not called in question the correctness of my statement of the general impression which prevailed among scientific men, alike when Mr. Crookes first exhibited his radiometer at the *soirée* of the Royal

Society, and when its phenomena were discussed at the subsequent meeting. Having followed that discussion with the greatest interest, I cannot now recall one word that was not in harmony with the "direct impact" doctrine, or that suggested the idea of "heat reaction" through residual gas. If the question had been then asked, whether the rotation would continue to take place in an *open* vacuum (were such possible), or in a *perfect* vacuum,—so as to eliminate all "reaction," through residual gas, between the vanes and the containing flask,—I believe that the general, if not the unanimous, verdict would have been in the affirmative. Certainly I heard nothing from Mr. Crookes on the other side, he having previously spoken of the dependence of the "Repulsion resulting from Radiation on the presence of residual gas as 'impossible to conceive.'"

It is clear, then, that in referring to this then prevalent view, I no more wished to put Mr. Crookes in the wrong, than I wished to put in the wrong my very excellent friends among the other eminent Physicists who shared it; the special purpose of this part of my paper being to bring out, as strongly as I could, *the thoroughly scientific and philosophical method in which Mr. Crookes afterwards worked himself right.* If this is not expressed in as much detail as Prof. G. C. Foster would have approved, it surely afforded no adequate ground for his going out of his way to charge me with having "depreciated Mr. Crookes's merits." Yet this is the *only* ground that I can find in the whole of Prof. Carey Foster's statement, for what I could not but regard as a very grave imputation.

On Mr. Crookes's reply I shall make but a single remark, with reference to his perfectly correct citation of the latter part of my conversation with him, on the occasion of his receiving the Royal Medal. If I had not found, after the publication of my Lectures (in which I said nothing but what was respectful to Mr. Crookes), that he had himself been "digging up the hatchet" which I was quite disposed to keep buried, by giving his public attestation to the "spiritualistic" genuineness of what had been proved to be a most barefaced imposture, I should not have again brought his name into the controversy. But I felt that his greatly increased reputation as a Scientific man would do an increasing injury to what I honestly believed to be the cause of reason and common sense, not only in this country but still more in the United States.

Since the death of Prof. Hare, not a single scientific man of note (so far as I am aware) has there joined the Spiritualistic ranks; but the names of the "eminent British scientists," Messrs. Crookes and Wallace, are a "tower of strength" to the various orders of "mediums"—rapping mediums, writing mediums, drawing mediums, materialising mediums, test mediums, photographic mediums, trance mediums, healing mediums, and the like—*whose names form many columns* of the "Boston Trades' Directory." And the now notorious impostor, Eva Fay, has been able to appeal to the "endorsement" given to her by the "scientific tests" applied to her by "Prof. Crookes and other Fellows of the Royal Society," which had been published (I now find) by Mr. Crookes himself in the *Spiritualist* in March, 1875. Within two months of that date, as Mr. Maskelyne has publicly stated, an offer was made him (I have myself seen copies of the letters) by Eva Fay's manager, that for an adequate sum of money the "medium" should expose the whole affair, scientific tests and all, "*complicating at least six big guns, the F.R.S. people,*" as she was not properly supported by the Spiritualists.

I have therefore felt it incumbent on me to show that in dealing with this subject Messrs. Crookes and Wallace have followed methods which are thoroughly *un*-scientific; and have been led by their "prepossession" to accept with implicit faith a number of statements which ought to be rejected as completely untrustworthy.

My call to take such a part—which I would most gladly lay aside for the scientific investigations which afford me the purest and most undisturbed enjoyment—seems to me the same as is made upon every member of the Profession to which I have the honour to belong, that he should do his utmost to cure or to mitigate *bodily* disease. The training I originally received, and the theoretical and experimental studies of forty years, have given me what I honestly believe (whether rightly or wrongly) to be a rather unusual power of dealing with this subject. Since the appearance of my Lectures I have received a large number of public assurances that they are doing good service in preventing the spread of a noxious *mental* epidemic in this country; and I have been privately informed of several instances, in which persons who had been "bitten" by this malady, have owed their recovery to my treatment. Looking to the danger which threatens us from the United States, of an importation of a real spiritualistic *mania*, far more injurious to our *mental* welfare, than that of the Colorado beetle will be to our *material* interests, I should be untrue to my own convictions of duty if I did not do what in me lies to prevent it. That I do not take an exaggerated view of the danger, will be obvious to any reader of Mr. Home's book. I know too well that I thus expose myself to severe obloquy, which (as I am not peculiarly thick-skinned) will be very unpleasant to myself, and unfortunately still more so to some who are nearly connected with me. But I am content to brave all, if I can believe that my *exposé* will be of the least service either to individuals or to society at large.

W. B. CARPENTER

THE high scientific position which Prof. Foster holds, as well as the decided manner in which his letter was written, must lead the otherwise unbiassed reader to the conclusion that not only has a satisfactory explanation of the action in question been found and generally adopted, but that this explanation turns upon certain considerations, and particularly on the mean length of the path of the gaseous molecules as influenced by the degree of rarefaction.

I feel my position, therefore, particularly unfortunate in having, for the sake of truth, to show that the explanation which Prof. Foster has adopted, and supposes others to have adopted, is, if judged by the statements in his letter, inconsistent with well-established laws.

Prof. Foster gives me credit for having originated the fundamental idea of the explanation, but states that my "explanation was theoretically incomplete; in particular it did not show clearly why so high a degree of rarefaction should be necessary for the production of the phenomenon in question;" and then he proceeds to explain how this asserted deficiency was supplied by other thinkers, who showed that "the increase, resulting from rarefaction, in the mean length of the path of the gaseous molecules, would favour the action."

It is this supposed completion of my explanation that is erroneous. It is contrary to the law of the diffusion of heat in gases that "the increase, resulting from rarefaction, in the mean length of the path of the gaseous molecules would favour the action," and so far from supplying any deficiency in my explanation it is incompatible with it. The only result from such an increase is to diminish the action—a result which rises into importance only when the rarefaction is carried so far that the mean length of the path of a molecule becomes comparable with the dimensions of the inclosing vessel.

In my first paper I gave a definite proof, which has nowhere been questioned, that according to the kinetic theory the force arising from the communication of heat from a surface to adjacent gas of any particular kind depends only on one thing, the rate at which heat is communicated, and to this it is proportional. If therefore the increased rarefaction increased the force it must increase the rate at which heat is communicated, but according to the law established by Prof. Maxwell the rate at which heat is communicated is independent of the density of the gas, whence it follows that the increase in the mean length of the path of the gaseous molecules, resulting from rarefaction, cannot favour the action which remains approximately constant until the gas becomes so rare that the law of diffusion no longer holds, after which it may easily be shown the communication of heat, and hence the action in question, diminishes but never increases.

The fact that in the radiometer the force caused by the communication of heat only causes motion when the surrounding gas becomes extremely rare is, as I pointed out in my first papers, fully explained by the action of what I have called convection currents, which action depends on the weight and density of the gas. The gas adjacent to the hot surface is hotter than that which is more remote, and hence the former rises forming an ascending column, to supply which the gas is drawn in laterally on all sides, and tends to carry the surface forward with it. With the same difference of temperature and surrounding circumstances the speed of these convection currents is the same whatever may be the density of the gas, and hence the force which they exert on the surface is proportional to the density of the gas.

This force is opposite in direction to that arising from the communication of heat to the gas, and since the former diminishes with the density while the latter is constant, there must be some density for which they balance, and below which the constant force will predominate, while above this point the convection currents will carry the surface with them. The fact that [...]arting from low densities, the motion of the vanes in the radio[m]eter does not only diminish as the density increases, but is [a]ctually reversed at higher densities, requires explanation, and [n]o other than this has yet been offered.

I have gone into the subject at considerable length, as I felt [b]ound, when venturing to differ from so high an authority as Prof. Foster, to state my reasons. There is, however, nothing in what I have said here which I have not said elsewhere, in the same or other words; and however incomplete in theory the explanation given in my first papers may be, I can only say that it included all the facts known to me at the time these were written; it has led me to predict many of the experimental results which have since been obtained, and I have not been able to find one fact with which it is not in accordance, nor has it been, so far as I am aware, controverted in any particular.

OSBORNE REYNOLDS

47

insects, and then, after noticing the Chermes that attacks that very strong food the larch, we come to a full description of *Phylloxera vastatrix*. The Hemiptera are shortly mentioned, and then the Myriopoda. There is a good picture of Geophilus clinging around its great prey, a large earthworm, and also of a Polydesmus. Amongst the Scorpions the long-armed Phrynus and Gonoleptes, and amongst the Spiders a long Tetragnatha and the extraordinary-bellied Gasteracantha, form admirable illustrations. A short chapter on Pycnogonum and Nymphon concludes this really wonderful volume.

P. M. D.

OUR BOOK SHELF

Heat. By B. Loewy (Lardner's Handbook of Natural Philosophy. Crosby Lockwood and Co., 1877.)

THIS, though not a bulky book, is a sort of miniature Encyclopædia of the subject. So far as we have read it it seems to have all the faults of the original (?) work to which Lardner's name was prefixed, with the important exception of the inaccuracies. These have been to a great extent removed, and the work has been brought up to date, but there is still the woeful want of order, or indeed of any guiding principle whatever which distinguished the former editions. It is a very curious mixture of good and bad, and cannot be called, in any sense, attractive to the reader. Numerous tables of experimental data are given, but they are in many cases carried to a number of places of figures quite beyond the present power of experimental science. Two, or perhaps three of the figures in the earlier places of each number are probably correct; the others give a show of minute accuracy which may altogether deceive the beginner. The treatment of the theoretical part is very meagre, but in the experimental part many curious facts not usually known are given. The book may be useful as a work of reference to those who are not in possession of Balfour Stewart's treatise, but we cannot say more in its favour.

Ferns, British and Foreign. The History, Organography, Classification, and Enumeration of the Species of Garden Ferns, with a Treatise on their Cultivation. By John Smith, A.L.S., Ex-Curator of the Royal Gardens, Kew. New and Enlarged Edition. (London: Hardwicke and Bogue, 1877.)

THAT Mr. Smith's "Ferns, British and Foreign" should have reached a new edition in a comparatively short time is no small tribute to its value as a book of reference for amateurs and fern cultivators. The chief portion of this very neatly got up work is occupied by an enumeration of cultivated ferns. The different genera, as understood by the author, who was one of the foremost pteridologists of his day, are described and figured, while a list of the cultivated forms, with synonyms and range of geographical distribution, follow under each genus, no attempt being made to give a diagnosis of the species. The scope of the work is therefore entirely different from that of the "Synopsis Filicum" of Hooker and Baker. The classification adopted is that propounded by Mr. Smith in his early publication on ferns, an arrangement not much used by modern writers. An appendix of recently-introduced ferns is given. These have been collected and arranged under their respective genera and tribes, as their names have from time to time been noticed in the horticultural journals and in nurserymen's catalogues. The list has thus no pretensions to be a critical one. The most interesting part of the book is the history of the introduction of exotic ferns, a subject about which, probably, no man living knows more than Mr. Smith. This is followed by an explanation of terms used in describing ferns, perhaps the least satisfactory part of the whole volume, as many of the terms are more or less obsolete, or only used in the book now before us. In this section nothing is said about the recent researches into the nature of the prothallus, construction of the reproductive organs, and morphological nature of the sporangia. The last part of the work is occupied by an essay on the cultivation of ferns, reprinted without alteration from the first edition, but giving the results of long experience of the successful cultivation of all groups of ferns. As a work of reference and guide to the cultivation, this book will most undoubtedly be of great service to the fern-growing public.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to ensure the appearance even of communications containing interesting and novel facts.]

The Radiometer and its Lessons

I HAVE little doubt that Prof. Osborne Reynolds is much more competent than I am to say what is or is not consistent with the kinetic theory of gases, but I hardly think that he gives evidence of this in his letter to last week's NATURE (p. 27). Unless my ignorance of the matter is more complete than I am aware of, the law that the rate of communication of heat to a gas is independent of the density, applies only when the space occupied by the gas is so great, or the variations of density so small, that these variations do not alter the temperatures of those portions of the gas which are at each instant respectively receiving and giving out heat. This condition cannot, I imagine, be fulfilled in the radiometer, where it seems to me inevitable that an action of the kind to which Mr. Johnstone Stoney called attention must take place.

G. CAREY FOSTER

P.S.—Since writing my previous letter to NATURE, a fortnight ago, I have read a paper by Mr. R. Finkener, in *Poggendorff's Annalen* (vol. clviii. pp. 572–595). This paper contains, besides a theoretical investigation of the motion of the radiometer founded on the kinetic theory of gases, an experimental proof that the action becomes much less when an extremely high degree of rarefaction is reached. The paper itself is not dated, but, as the Part of the *Annalen* which contains it was "closed" on July 31, 1876, the experiments described in it cannot have been much, if at all, subsequent to those (communicated to the Royal Society, June 13, 1876) which led Mr. Crookes to a like result.

G. C. F.

UNTIL I read Dr. Carpenter's letter in your issue of the 8th inst., it had never occurred to me that his "special purpose" was to bring out strongly my "thoroughly scientific and philosophical method!" This is an act of disinterested kindness which recalls to me the exquisite truth of Dean Swift's remark, "No enemy can match a friend."

Dr. Carpenter's only reply to my letter which appeared in your issue of the 1st inst. is contained in the following passage:—"If I had not found," he says, "after the publication of my Lectures, that he had himself been 'digging up the hatchet,' which I was quite disposed to keep buried, by giving his public attestation to the 'spiritualistic' genuineness of what had been proved to be a most barefaced imposture, I should not have again brought his name into the controversy."

Further on Dr. Carpenter paraphrases passages from his article in *Fraser's Magazine* for this month, in which he goes more into detail touching this "public attestation," of which in his eyes I stand accused.

"Eva Fay," he says, "returned to the United States, carrying with her a letter from Mr. Crookes, which set forth that since doubts had been thrown on the Spiritualistic nature of her 'manifestations,' and since he in common with other Fellows of the Royal Society had satisfied himself of their genuineness by 'scientific tests,' he willingly gave her the benefit of his attestation. This letter was published in *facsimile* in American newspapers."

My answer to this calumny shall be brief.

It is untrue that I dug up the hatchet—Dr. Carpenter's

48

Uses of Crooke's Mill.

Dec 77

CONTINUED FROM PAGE 311.

Photographers may also derive great benefit from the use of Crooke's mill in their dark rooms, where they use an orange-colored glass to admit daylight. They will notice a certain slow velocity of the instrument when exposed to this light; having ascertained by experiment, once for all, what the safe velocity is, beyond which the light is so strong that his plates become foggy or his sensitized paper injured, he may take care in the future to diminish the light as soon as as the instrument revolves beyond this velocity by a too strong sun or day light penetrating the yellow glass. Suppose he finds that with 12 revolutions per minute the light has effect, he will look out that when the instrument revolves with a velocity beyond 10, to draw his curtain.

In meteorological observations everything is at present accurately recorded—temperature, atmospheric pressure, rain-fall, force of wind, etc.; but the only thing thus far roughly guessed at is the amount of light prevailing. No doubt this light is as influential upon animal and vegetable life as any of the other agencies, and for the progress of science and its useful application to agriculture and sanitary regulations, it should be as accurately recorded as the other observations.

The instrument in question now gives a direct measure, quite different from a mere rough estimate thus far followed. It is simply placed on a high building or mountain, and connected by telegraph wires to a central observatory, where then an exact account can be kept of the proportion of sun-light received, and compared with similar observations in various latitudes and different heights above the level of the sea.

It is evident that such observations are closely related to those of temperature. The latter depends greatly on the amount of rays which a locality receives from the sun, and also on atmospheric currents of different temperatures which pass over it, and of ocean currents of warm or cold water which pass in its neighborhood. Thermometrical observations alone do not enable us to discriminate between these different causes; but the radiometer will enable us to distinguish how much of the annual temperature of a place is due to direct solar radiation, and how much to winds and ocean currents.

The transmission of the velocity of revolution by telegraph wire may be arranged by making one of the axes a steel magnet, or suspending such a one to one of the vanes; another magnet in the form of a bar or compass-needle is placed outside, delicately suspended on its center, and by every revolution of the instrument it is moved by the magnet carried on one of the vanes, and revolving with them. This motion of the outside compass-needle makes and breaks contacts, and so sends alternate currents, one for every revolution, which, by means of a Morse telegraph, makes dots upon a ribbon of paper regularly moved by clock-work. The distance of the dots will of course be proportional to the number of revolutions; they will be far apart when there is a little light, and closer together in proportion as the light is stronger.

If this instrument is not sensitive enough to be started by light alone, which is very likely to be the case, when the magnets manifest their attraction forcibly, it may be started from headquarters by means of a battery current acting on a small electro-magnet placed outside the instrument; a single contact will manifest a sudden attraction to the movable magnet and start a motion in the same, which may give it an impetus which will be kept up by the influence of the light. The record thus kept may be represented as follows:

. . . .

Record of a weak illumination at daybreak.

. . . .

Record of illumination of a cloudy sky.

. . . .

Record of illumination of sunshine in the early morning.

....

Record of illumination by sunlight at noon.

The law that the intensity of light is in an inverse ratio to the square of the distance may be also recorded by the method just described. Place a candle 4 inches from the instrument, and if the dots are then say ½ an inch apart, place the candle at 5⅔ inches, and they will be 1 inch apart; at 8 inches they will be 2 inches apart; at 10 inches they will be 3⅛ inches apart. Now these distances of the dots—½, 1, 2, and 3⅛—are in a ratio to the squares of the distances, 4, 5⅔, 8, and 10, which are 16, 32, 64, and 100, or dividing all these by 32 we obtain ½, 1, 2, and 3⅛, proving that the instrument acts according to the law.

CERTAIN MOVEMENTS OF RADIOMETERS[1]

NEARLY two years ago Mr. Crookes was so good as to present me with two of his beautiful radiometers of different constructions, the discs of one being made of pith, and those of the other of roasted mica, in each case blackened with lampblack on one face. With these I was enabled to make some experiments, having relation to their apparently anomalous movements under certain circumstances, which were very interesting to myself, although the facts are only such as have already presented themselves to Mr. Crookes, either in the actual form in which I witnessed them, or in one closely analogous, and have mostly been described by him. Although it will be necessary for me to describe the actual experiments, which have all been repeated over and over again so as to make sure of the results, I do not bring forward the facts as new. My object is rather to endeavour to co-ordinate them, and point to the conclusions to which they appear to lead.

I do not pretend that these conclusions are established; I am well aware that they need to be further confronted with observation; but as I have not leisure to engage in a series of experiments which would demand the expenditure of a good deal of time, and have lately been urged by a friend to publish my views, I venture to lay them before the Royal Society, in hopes that they may be of some use, even if only in the way of stimulating inquiry.

In describing my experiments I will designate that direction of rotation in which the white face precedes as positive, and the reverse as negative. It will be remembered that, under ordinary circumstances, radiation towards either radiometer produces positive rotation.

1. If a glass tumbler be heated to the temperature of boiling water, and inverted over the mica radiometer, there is little or no *immediate* motion of the fly, but quickly a *negative* rotation sets in, feeble at first, but rapidly becoming lively, and presently dying away.

2. If after the fly has come to rest the hot tumbler be removed, a *positive* rotation soon sets in, which becomes pretty lively and then gradually dies away as the apparatus cools.

3. If the tumbler be heated to a somewhat higher temperature, on first inverting it over the radiometer there is a *slight positive* rotation, commencing with the promptitude usual in the case of a feeble luminous radiation, but quickly succeeded by the negative rotation already described. If the tumbler be heated still more highly, the initial positive rotation is stronger, and lasts longer, and the subsequent negative rotation is tardy and feeble.

4. If the pith radiometer be treated as in § 1, the result is the same, with the remarkable difference that the rotation is positive instead of negative; it is also less lively.

[1] Paper read at the Royal Society, December 20, by Prof. G. G. Stokes, Sec. R.S.

49

5. But if the tumbler be removed when the fly has come to rest, it remains at rest, or nearly so.

6. If the tumbler be more strongly heated, positive rotation begins as promptly as with light. In this case the tumbler must not be left long over the radiometer, for fear the vacuum should be spoiled by the evolution of gas from the pith.

7. If the tumbler be heated by holding it over the spout of a kettle from which steam is issuing, and held there till the condensation of water has approximately ceased, and be then inverted over the pith radiometer, the bulb is immediately bedewed, and a *negative* rotation is almost immediately set up, though sometimes, just at the very first moment, there is a trace of positive rotation. The negative rotation is lively, but not lasting; and after fifteen seconds or so, is exchanged for a positive rotation, which is not lively, but lasts longer.

8. If the tumbler be lifted when the negative rotation has ceased, and the dewed surface be strongly blown upon, a lively but brief positive rotation is set up.

9. To produce positive rotation by blowing it is not *essential* that the bulb be wet. If it be merely warm, and the circumstances are such that the fly is at rest for the moment, or nearly so, blowing produces positive rotation, though much less strongly than when the bulb is wet.

10. If the tumbler be heated as in § 7, and inverted over the mica radiometer, the rotation is positive, as when the tumbler is dry.

11. If the tumbler or a cup be smoked inside (to facilitate radiation), heated to a little beyond the temperature of boiling water, and inverted over the pith radiometer, a positive rotation is produced; and if, when this has ceased, which takes place in a couple of minutes or so, the heated vessel be removed, a negative, though not lively, rotation is produced as the apparatus cools.

12. These results do not seem difficult to co-ordinate so far as to reduce them to their proximate cause.

As regards the small quantity, if any, of heat radiated directly across the glass of the bulb, the action of which was experimentally distinguishable by its promptitude, both radiometers behaved in the ordinary way.

13. As regards the mica radiometer, when the bulb gets heated and radiates towards the fly the fly is impelled in the negative direction *as if* the white pearly mica were black and the lampblack were white. And there is nothing opposed to what we know in supposing that such is *really* their relative order of darkness as regards the heat of low refrangibility absorbed and radiated by the glass; for the researches of Melloni and others have shown that lampblack is, if not absolutely white, at any rate very far from black as regards heat of low refrangibility. On the other hand, glass and mica are both silicates, not so very dissimilar in chemical composition, and it would not therefore be very wonderful, but rather the reverse, if there were a general similarity in their mode of absorption of radiant heat, so that the heat most freely radiated by glass and accordingly abounding in the radiation from *thin* glass such as that of the bulb, were greedily absorbed by mica. The explanation of the reversal of the action when heat and cold were interchanged is too well known to require mention.

14. With the pith radiometer, when the bulb as a whole is heated, and radiates towards the fly, the impulse is positive, though less strong than in the case of the mica (§ 4); and when the bulb as a whole is cooler than the fly the impulse is negative (§ 11).

But to explain all the phenomena we must dissect the total radiation from or towards the bulb. When I first noticed the negative rotation produced by a heated wet tumbler, I was disposed to attribute it to radiation from the water, which possibly the glass of the bulb might be thin enough to let pass; but when I found that hot water in a glass vessel outside, even though the glass of it were thin, produced no sensible effect, and that blowing on the heated bulb when it was dry produced a similar effect to blowing on it when dewed, though of much less amount, I perceived that the moisture acted, not by direct radiation from it, and in consequence of a difference of quality between the radiations from glass and water, but by causing a rapid *superficial* heating of the bulb; and, similarly, the blowing on the dewed surface acted by causing a rapid superficial cooling. When the dry tumbler radiates to the bulb, the radiation is absorbed at various depths; the absorption is most copious, it is true, at the outer strata, but still the change of temperature is not by any means so much confined to the immediate surface as when we have to deal with the latent heat of vapour condensed on it, or obtained from it by rapid evaporation.

Hence, thin as is the glass of the bulb (about 0·02 in. thick), we must still, in imagination, divide it into an outer and inner stratum, and examine the effects of these separately. The heat radiated by either stratum depends only on its temperature, but the radiation from the outer, on its way to the fly, is sifted by passing through the inner, and the portion for which glass is most excessively opaque is in great part stopped. It appears from the observed results that the residue acts decidedly negatively, while when the bulb is pretty uniformly heated there is positive action. We may infer that if it were possible to heat the inner stratum alone it would manifest a very decided positive action.

15. In the struggle between the opposing actions of the outer and inner strata we see the explanation of the strange behaviour of the pith radiometer. In the experiment of § 7 the outer stratum at first shows its negative action, but quickly the inner also gets heated, partly by conduction from the outer, partly by direct radiation from the tumbler, and then the inner prevails. In the experiment of § 5 the whole bulb cools, partly by radiation, partly by convection, while the fly remains warmer; and the slightly greater coolness of the outer than of the inner stratum makes up for the superiority of the inner when the two are equally cool, so that the antagonistic actions nearly balance, and slight causes, such as greater or less agitation of the air, suffice to make the balance incline one way or other. That the inner stratum *would* prevail if the two were about equally cooled may be inferred from the behaviour of the radiometer when the bulb is pretty uniformly heated (§§ 4, 11), or shown more directly by cooling the bulb with snow, when a negative rotation may be obtained.

16. The complete definition of a radiation would involve the expression of the intensity of each component of it as a function of some quantity serving to define the quality of the component, such as its refractive index in a standard medium, or its wave-length, or the squared reciprocal of the wave-length.[1] The experimental determination of the character, as thus defined, of a radiation consisting of invisible heat-rays is beset with difficulties, at least in the case of heat of extremely low refrangibility; and in general we can do little more than speak in a rough way of the radiation as being of such or such a kind. It is obvious that the behaviour of radiometers by itself alone affords no indication of the refrangibilities of the kinds of heat with which we have to deal; nevertheless, by combining what we know of the behaviour of bodies in respect to radiations in general (especially luminous radiations, which are the most easily studied) with what we observe as to the motions of radiometers, we may arrive at some probable conclusions.

17. We may evidently *conceive* a series of ethereal vibrations of any periodic time, however great, to be incident on a homogeneous medium such as glass, and inquire in what manner the rate of absorption would change with the period; though whether we can actually *produce* ethereal vibrations of a very long period is another question, seeing that we can only act on the ether by the intervention of matter, and are limited to such periods of vibration as matter can assume when vibrating molecularly, in a manner communicable to the ether, and not as a continuous mass, in the manner of the vibrations which produce sound. We may inquire whether, on continually increasing the period of vibration, the glass (or other medium) would ultimately become and remain very opaque, or whether, after passing through a range of opacity, it would become transparent again, on still further increasing the period of the incident vibrations.

18. This is a question the experimental answer to which, as it seems to me, could only be given, in so far as it could be given at all, as a result of a long series of experiments, of a kind that Melloni has barely touched on. A variety of considerations, which I could not explain in short compass, lead me to regard the second alternative as the more probable, namely, that, on increasing the periodic time, homogeneous substances in general (perhaps even metals, though this is doubtful) become at last transparent, or at least comparatively so. The limit of opacity, in all probability, varies from one substance to another; and the lower it is, the lower would be the lowest refrangibility of the radiation which the same substance is capable of emitting.

19. In what immediately follows I shall suppose accordingly that glass is strongly absorbing through a certain range of low

[1] A map of the spectrum, constructed with the squared reciprocals of the wave-lengths for abscissæ, would be referred to a natural standard, no less than that of Ångström, which is constructed according to wave-lengths; while it would have the great advantage of admitting of ready comparison with refraction spectra, the kind almost always used.

perature of the interior surface of the fly will be less attracted, or, which is the same, more repelled. Hence, whether the inner surface of the bulb be cooler or hotter than the fly, a reversal in the direction of rotation while the fly is being heated, indicates a reversal in the order of absorbing power of different

The Radiometer and its Lessons

78

WITH reference to the controversy between Mr. Stoney and Mr. Osborne Reynolds about the laws of the conduction of heat in gases, it seems desirable to call the latter gentleman's attention to the fact that neither Clausius' nor Clerk Maxwell's investigations, as published in the *Philosophical Magazine*, affect the controversy between them.

The latter, in his papers in the *Philosophical Magazine*, vol. xxxv., lays particular stress upon the fact that he supposes the motions of the molecules to be uniformly distributed in every direction. He says, however, on page 188: "When one gas is diffusing into another, *or when heat is being conducted through a gas*, the distribution of velocities will be different in the positive and negative directions instead of being symmetrical, as in the case we have considered." From this theory of the uniform distribution of velocities he deduces the formula (29), (31), and (32), as he numbers them, and to which he subsequently refers. On page 214 he gets an equation (143) which represents the transference of heat through the medium, and says: "The second term contains quantities of four dimensions in $\xi\,\eta\,\zeta$, *whose value will depend upon the distribution of velocity* among the molecules. *If* the distribution of velocity is that which we have proved to exist when the system has no external forces acting on it, and when it has arrived at its final state we shall have by equations (29), (31), (32) . . ." certain results from which he deduces his equation for the conduction of heat in gases.

When he says "has arrived at its final state" it is evident from his reference to the equations that he means the state of a gas in which neither diffusion nor conduction of heat nor currents of any kind are going on. It will thus be seen that his final result is only a first approximation and could not possibly be expected to hold within distances comparable with the mean length of the path of a molecule between two encounters.

Clausius in his paper as translated in the *Philosophical Magazine* for June, 1862, does suppose a distribution of velocity among the molecules of such a kind that the velocity and number of molecules moving in the positive and negative directions is different, but assumes the mean between them to be the same as the number moving in a direction normal to the direction of the transference of heat. This is evident from the fact that what he practically does is to assume that the number of molecules moving in a direction making an angle θ with the direction of transference of heat can be expressed by a formula of the form—

$$n = n_0 (1 + e \cos \theta),$$

for he neglects e^2 throughout his investigation. In this form it is evident that n_0 is the number when $\theta = \frac{\pi}{2}$ and is the mean of the values $n_1 = n_0(1 + e)$ and $n_2 = n_0(1 - e)$, which represent the numbers going towards and from the points of high temperature. From the fact that e^2 enters into the investigation at all it is evident that this is only an approximation to the true distribution. In accordance with this Mr. Stoney has shown conclusively that in a compressed Crookes's layer the number of molecules moving parallel to the direction of the transference of heat is greater than the number of those moving in any direction normal to it, so that the expression Clausius derived from his assumption cannot be considered as expressing the whole state of affairs.

It is remarkable that to this order the expression for the pressure on *any* plane is the same, but Clausius gives another term in his expression for the pressure on a plane normal to the direction of transference of heat to which he attaches, indeed, only an indefinite coefficient because it is of the order e^2, and he was purposely neglecting quantities of that order. He might have prophesied, however, from the existence of such a term that at distances comparable with e a force would be manifested such as Mr. Crookes has since discovered. Now this e is by definition a quantity of the order of the length of the mean path between successive encounters, and hence these terms, varying with e^2 would become of importance at distances comparable with the length of this mean path.

I believe, then, that I have shown that neither Clausius nor Clerk Maxwell have considered the case in dispute between Mr Stoney and Mr. Osborne Reynolds, and that as far as their investigations bear upon it they tend very much to strengthen Mr. Stoney's case. I have also shown that Clausius was on the point of anticipating both Crookes's force and Mr. Stoney's explanation of it.

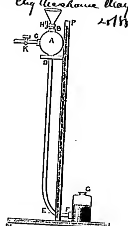
GEISSLER AIR-PUMP.

[17360.]—Of all the air-pumps, the Geissler mercury pump is, without doubt, the most easily

Eng Mechanic

constructed by the inexperienced amateur. No piston to make, no metal work to do. With such a pump as that we will describe, a first-class vacuum is got, and very delicate experiments may be performed. We have dispensed with the usual gear work and three-way taps, and have made a very simple form of the apparatus. The glass globe A has three openings, viz., the neck at D, and two openings at B and C. This globe, in our machine, has 2½in. diameter. It may be bought at any chemical apparatus warehouse. The openings at B and C are fitted with indiarubber "corks," each having a hole. Thus we fit at B a brass funnel, with stopcock, and at C a glass tube,

Eng Mechanic May 28 1880



having also a stopcock. On to the neck D we fix an indiarubber tube D E, about one yard long, which communicates with the mercury bottle by the lower tubulure F. This tube should be made of good and thick rubber, in order to withstand the weight of the mercury. In our machine, we have made it double, in order to avoid accidents, as it is very unpleasant to have to hunt about for 8lb. of mercury spilled over the floor of a room.

The apparatus is worked as follows:—The flask or tube to be emptied of air is connected with the lateral tube C K. The stopcock K is closed, H is opened, the mercury bottle F G is lifted, until the mercury, after having filled the globe A, comes up into the funnel. The stopcock H is then closed, and the mercury bottle put down on the base-board M N. The mercury then leaves the globe A in a state of vacuity, and descends a short way in the tube D E (the difference of the level in the tube and in the bottle is equal to the barometric pressure at that moment). We then open K, and hear the air rush from the flask we exhaust into A. This operation must be repeated several times. It takes, of course, longer to perform than a stroke of the piston of an ordinary air-pump; still, we do not think it too tiresome, and are very satisfied with our new machine. Those who are good hands at glass-working can dispense with the India-rubber cocks, and blow the funnel and stopcock tube directly on to the glass globe.

The globe A will cost about 1s. 6d.; the stop-cock funnel, 3s.; the stopcock-tube, 3s.; the mercury bottle 1s.; and about 28 shillingsworth of mercury (say 7lb.) will be required. The mercury can, of course, be taken out of the apparatus, when wanted, and used for a gas-trough.

The Radiometer and its Lessons

PROF. OSBORNE REYNOLDS arranges his last letter (NATURE, vol. xvii. p. 220) under four numbered heads, and in the reply which I appear called on to make I will follow this division.

1. In the first section he says, "There is nothing in my earlier papers that is 'admittedly erroneous.' If there is error in these papers I am not aware of it." This is strange. In his first paper (*Proceedings*, Royal Society, vol. xxii. p. 401) Prof. Reynolds declares its object to be "to point out and to describe experiments to prove that these effects (the motions observed by Mr. Crookes) are the results of evaporation and condensation." Now they are not the results of evaporation and condensation: and it might have been seen, *ab initio*, that evaporation and condensation could have had nothing to do with them; for evaporation and condensation can only produce a temporary force, ceasing so soon as the distillation is complete, and cannot therefore be any part of the cause of a persistent force such as that detected by Mr. Crookes, which lasts for any length of time during which the heat is applied. In the same paper Prof. Reynolds further says, "The reason why Mr. Crookes did not obtain the same results within a less perfect vacuum [than that of the Sprengel pump], was because he had then too large a proportion of air, or non-condensing gas, mixed with the vapour, which was also not in a state of saturation." All this is manifest error. But this is not all, for *the whole of the theory* of those papers is erroneous; neither condensable vapour nor residual gas acts in the way described by Prof. Osborne Reynolds. In investigating the force arising from evaporation and condensation, he has overlooked the circumstance that the evaporation from the disc will keep back part of the vapour which would otherwise have reached it, and in investigating the effect of condensation he tacitly assumes that it does keep it back. Now in both cases the reverse of the assumption is what takes place, and he actually arrives at the absurd result that "if the opposite sides of a pith ball in vapour were in such different conditions [*i.e.*, one surface evaporating, the other condensing] the ball would be forced towards the colder side" (p. 401). His conclusion amounts to this: that the recoil of a cannon would be doubled if it were struck from behind by a missile at the same moment that it discharges an equal mass with equal velocity forwards! If he had not made these mistakes he would have got out only the forces which result from "the perceptible motion of the vapour," which he states "would be insensible" (p. 403), along with alterations in the general tension of the vapour *which would act equally on both sides of the disc*. Those errors vitiate the whole of his mathematical reasoning, so that the value for f which he gets, is not, as he supposes, "the force arising from evaporation," and his law connecting it with the heat falls to the ground. I have all along supposed, from Prof. Reynolds's having long ceased to mention his theory of evaporation and condensation, that he was aware of some of its errors.

The same error vitiates his reasoning in reference to the action of residual gas. If the error is corrected, and if, as he assumes, the gas coming up to the disc had been unpolarised (*i.e.* had brought to the disc equal numbers of molecules, and with equal velocities from all directions in front), his investigation *would only have given him an increase in the general pressure of the gas*, acting, as I pointed out in paragraph 5 of my first paper (*Phil. Mag.*, March, 1876, p. 179), equally on the front and back of the disc, except during the almost inappreciable instant of adjustment. *Prof. Osborne Reynolds therefore wholly missed the source of the persistent force with which Mr. Crookes's experiments deal.*

2. Prof. Osborne Reynolds next says that his second paper "does not conclude with his own expression of opinion that residual gas is not the cause of the force observed by Mr. Crookes." In reply I have only to quote the concluding words of that paper (*Phil. Mag.*, November, 1874, p. 391). After passing under review the two agencies (condensable vapour and residual gas), which he supposes are to be considered, he decides in favour of the former in the following words: "hence in such cases [*i.e.*, under the conditions which he supposed to prevail in Mr. Crookes's experiments] it seems to me that the effects must be due to the forces of condensation."

3. In the next section of his letter Prof. Reynolds states that Clausius and Maxwell "established the law that the only condition of thermal equilibrium in a gas is that of uniform temperature." I am not aware that they have ever established this law. The converse of it is obviously true, and has often been used, and the law itself has sometimes been assumed, but has never, so far as I know, been proved. I am, however, disposed to concur with those who think that it is probably true, and the conclusion in my paper on penetration (which is the reverse of that attributed to me by Prof. Reynolds) is in conformity with it. My conclusion is expressed in the following words (*Phil. Mag.*, December, 1877, § 4):—"Hence there must, in the cases that really arise, be some escape of heat which may be small but cannot vanish." And, I may remark, there will, according to my view, be two other sources of escape of heat, viz., conduction by diffusion, which was excluded from my investigation; and conduction by radiation, which was excluded both from Clausius's investigation (*Phil. Mag.*, June, 1862, p. 422, footnote) and from mine.

Prof. Osborne Reynolds a second time objects to my having excluded conduction when investigating the penetration of heat. As he attaches weight to authority he will perhaps be reconciled to my doing so, by the example of Clausius, as cited above, and by his justification of it in the following words (*loc. cit.*):—"In any case, however, it is allowable to consider separately each of these two ways in which heat moves."

Before passing from this subject I wish to take the opportunity of stating that Dr. Schuster's letter (NATURE, vol. xvii. p. 143) has satisfied me that I have hitherto erred in my estimate of the relative efficiency of penetration and conduction as agents for conveying heat. I am now convinced that penetration is usually feeble compared with conduction, and, in the figures representing De la Prevostaye and Desains' experiments, is to be sought in those portions of the curves which slope steeply downwards. The second part of my paper on penetration, that in which I apply the theory to experiment, will accordingly require considerable modification; and some of the statements which I made in my papers on Crookes's force will need amendment. The corrections that are required do not, however, affect any of the material parts of my theories of Crookes's force and of penetration, which depend essentially on the fact that there is a layer in the gas extending to a limited distance from a heater or cooler, throughout which the effects of the discontinuity in the gaseous motions at the surface will be felt, and that within that layer the stresses and the communication of heat follow special laws.

4. I have to express my great satisfaction at the explicit admission made by Prof. Osborne Reynolds in the fourth section of his letter, in the following sentences:—"There is one statement in Mr. Stoney's letter which is not erroneous. He says, 'I cannot find anywhere in Prof. Osborne Reynolds's writings an explanation of the thing to be explained, viz., that the stress in a Crookes's layer is different in one direction from what it is at right angles to that direction.' I [Prof. Osborne Reynolds] do not at all admit that this is 'the thing to be explained,' and I am quite sure that Mr. Stoney would find no explanation of it in my writings." This admission disposes finally of all controversy as to priority between us.

I need hardly, after this admission, follow Prof. Osborne Reynolds through the rest of his letter. His supposed invariable law "that the [Crookes's] force always tends to drive the vanes or bodies in the direction of their colder faces," does not seem to be true. A familiar exception occurs when a spheroidal drop is supported over a platinum dish. The Crookes's force acting upon the platinum dish is equal to the weight of the drop, and acts downwards, *i.e.* in the direction of the *hottest* surface of the dish.

In applying his hypothetical case of a heater and cooler, A and B, within an envelope of intermediate temperature, to prove that "the force that causes the motion in the bodies cannot be due" to the stresses of my theory, he has overlooked the very obvious circumstance that the envelope, as well as B, is a cooler in reference to A, and the envelope, as well as A, is a heater in reference to B.

Prof. Reynolds observes that I have not defined polarisation. I described the kind of polarisation that exists in radiometers in my first two papers, and I will give a formal definition of the term as applied generally to gases in an article which I am preparing, and which I hope will be admitted into the pages of NATURE, giving as clear an account of my theory as I can, compatibly with brevity and the omission of mathematics.

The way in which Prof. Reynolds has excluded polarisation from his explanation is by assuming that the state of the gas close to the heated disc may be adequately represented by unpolarised gas of one temperature coming up to the disk, and unpolarised gas of another temperature leaving it, *i.e.*, by mole-

52

Law of the Absorption of Radiation through Bodies and on its Application in Quantitative Spectral Analysis (Second Part).—G. Govi.—Theoretic considerations, confirmed by experiment, have demonstrated to physicists that a mono-chromatic radiation, *i.e.*, one of a single wave-length, is extinguished by absorption, so that we have $I_1 = I k^x$, I representing the intensity of the incident radiation; I_r, that of the same radiation after its passage through a thickness, *x*, of the absorbent medium. The magnitude *k*, called the coefficient of absorption, and which is always fractional, expresses the intensity of the light which has traversed the unity of the thickness of the medium. This reaction enables us to calculate the value of *k* for any wave-length soever as soon as we know the ratio of the two intensities $\frac{I_t}{I}$ for a thickness *x* of the medium traversed. When the coefficients k_1 are once known nothing is easier than to apply them for tracing the curves of equal chromatic absorption, whether for a refraction spectrum or for the normal spectrum. For this it is sufficient to calculate *x*, giving to $\frac{I_r}{I}$ a constant value for all the different points of the spectrum, and employing for each point the corresponding coefficient of absorption. We may thus obtain as many points as we wish of the curve which corresponds to any intensity whatever, and construct by equidistant sections or by curves what may be called the surface of chromatic absorption in any given medium. Such researches cannot be made with an ordinary spectroscope, but a "photometer-analyser" must be applied, that is to say, an instrument by which the different simple radiations which form part of a complex radiation may be measured photometrically. If the principle of the photometer-analyser is once known, nothing is easier than to imagine for such an instrument very different arrangements which may almost equally well answer the end in view. It is sufficient to imagine a kind of spectroscope, the slit of which is divided into two parts longitudinally, and receives different radiations upon each half. If it is requisite to study absorption we leave one half of the slit free, and place before the other half a stratum of known thickness of the absorbent medium we wish to examine. The light coming from the two halves of the slit is decomposed by a prism into two spectra, which are in juxtaposition for their entire length, and one of which only has been modified by absorption. If we then endeavour to equalise these two spectra successively (by modifications of the slit, by polarising apparatus, or otherwise), at a very large number of points corresponding to determined wave-lengths, we obtain the measure of the intensity of the different radiations absorbed. When these intensities are once obtained we may deduce from them directly the coefficients of absorption corresponding to each radiation, and the form of the surface of chromatic absorption in the body which is under examination. If we have some coefficients of absorption of a substance dissolved in known quantity in a medium either non-absorbent, or having an absorbing power feeble and already measured, it is easy to determine the quantity of this same substance in another solution. It is merely requisite to take a stratum of the solution of known depth, and place it before the slit of the analytic photometer, measuring then the intensity of the radiations transmitted to know at once to what depth of the normal solution the same intensities would correspond, and consequently what is the quantity of the absorbent matter contained in the solution to be determined. Spectral analysis thus becomes a true method of quantitative analysis, and its applications are at once greatly extended. It must not be forgotten that this new method of analysis requires that we should be able to study all the radiations emitted or transmitted by different bodies. If we wish to confine ourselves to the study of the visible radiations, the utility of the method would be greatly reduced. But we substitute for the eye another organ, such as, *e.g.*, a thermo-electric battery, immediately substances which appear to absorb nothing in the luminous spectrum may manifest their presence in the ultra-red portion of the spectrum, and the means to determine their quantity is presented. A solution of aluminic sulphate is a case in point, and by the aid of the galvanometer the proportion of the salt contained in different solutions may be determined. The same will happen with the ultra-violet radiations, the intensity of which may be measured by the eye, by the aid of uranium glass, or of sulphate of quinine. If it is true, as a large number of observations appear to demonstrate sufficiently, that the luminous spectral lines of incandescent gases, or the dark lines which the same gases may determine by absorption in continuous spectra, are merely isolated and more intense summits of spectral curves of emission or absorption, quite similar to the curves of shade which absorbent solids and liquids produce, and if it is true that these lines may multiply and especially increase in breadth and intensity the condensation and the elevation of temperature of the bodies whence they spring, we comprehend that the determination of the luminous intensity at different points of a spectrum may serve to recognise the temperature and the density of the substance which emits or absorbs them, that is to say, to determine its quantity in a limited portion of space, provided that we have beforehand established the relation which connects the nature of the radiations emitted with the density and the temperature of the body under examination. Thus, then, by assimilating the phenomena of the emission- and absorption-spectra of gaseous bodies to those presented by the absorption-spectra of solids and liquids it does not appear impossible that we may succeed in obtaining quantitative analyses of bodies examined, even when such bodies escape ordinary methods of observation by reason of their tenuity or their remoteness. The "photometer-analyser" may still render other services to science. By applying it in the quantitative and qualitative analysis of the colours proper to different bodies we may hope to place the classification of colours upon an absolutely accurate basis.

THE CHEMICAL NEWS.

Vol. XXXII. No. 851.

DISCOVERERS AND ?

"Sic vos non vobis mellificatis apes."

It has more than once fallen to our lot to vindicate the claims of original discoverers in the pages of this journal. It sometimes happens that the same discovery is made by two men quite independently of each other. In such cases, although both may deserve equal credit, he who can prove priority of publication is acknowledged to be entitled to the honour attending the discovery.

It also sometimes happens that a discoverer, after his results have been not only published, but fully discussed in the scientific journals, finds them re-discovered, and laid before some illustrious society as an entire novelty, without the slightest reference to his labours. We have even known the "conveyer," as in the case of thallium, to accuse the original discoverer of appropriation.

It is not many years since we drew the attention of our readers to the fact of the well-known process of Parkes for the volumetric determination of copper being claimed by M. de la Follye as an improvement of his own upon the sulphide of sodium process of Pelouze, and, strange to relate, Pelouze himself actually described it as such in a memoir read before the Academy of Sciences. So far as we know—we shall be glad to be corrected if we are wrong—this claim has never been withdrawn, notwithstanding the indignant protests of German as well as English chemists. Now it is not to be expected that one man will surrender his claim until priority of discovery has been clearly established by another; but let this once be done, and he who desires to act honourably will at once concede to his rival the honour due to him. To act otherwise is dishonourable in the highest degree; nor is it, in our opinion, less dishonourable for one scientific man to endeavour to injure, or detract from, the reputation of another. We can understand feelings of national pride, and jealousy of national interests, leading men to leave no stone unturned in their endeavour to claim priority of discovery for a fellow-countryman, but we utterly fail to comprehend the motive which prompts a man to shift the credit of a discovery or an invention from a fellow-countryman to a foreigner. At the risk of being accused of obtrusiveness and egotism we feel bound to ask if this has not been the course pursued by Prof. Osborne Reynolds in his several notices of the Radiometer at the Manchester Literary and Philosophical Society. Prof. Osborne Reynolds we have always regarded as a man of singular ability, a physicist who, by earnest study and close application, has attained to an honourable position in the scientific world. His opinion on subjects connected with mechanical and physical science deservedly commands attention, and it is because we entertain these views of his scientific attainments that we think it necessary to point out what would seem to be a studied injustice unworthy of his present position.

The facts of the case are simple. In December, 1873, the first part of a paper "On Attraction and Repulsion Resulting from Radiation" was read before the Royal Society. The experiments therein described led to the construction of an instrument, which is now well known as Crookes's Radiometer, which was first exhibited at the *Soirée* of the Royal Society on the 7th April, 1875. In December, 1875, our attention was directed to an advertisement in *Nature*, in which Mr. Browning announced that he had been appointed sole agent for a new Radiometer made by Herr Geissler. We at once called on Mr. Browning, and he saw that the advertisement gave undue credit to Herr Geissler, and readily made the necessary alteration.

In January, 1876, it was announced by the Secretaries of the Manchester Literary and Philosophical Society (Prof. Osborne Reynolds and Mr. Baxendell) that at the next meeting Prof. Osborne Reynolds would exhibit and explain Crookes's Radiometer. In the report of the meeting on the 25th January, however, the instrument is described as "Geissler's light-mill." On the 17th February it is announced by circular that at a meeting of the Society on the 22nd inst. Prof. Reynolds will show some further illustrations with reference to the action of "Geissler's light-mills."

Any person unacquainted with the circumstances might infer from the above programme that the "light-mill" was a new and independent discovery of Herr Geissler; yet all the time it is simply the radiometer which has been exhibited before the Royal Society and the Royal Institution. Herr Geissler certainly makes radiometers so as to bear transportation, according to a suggestion given him by the inventor through Prof. Zöllner. The latter distinguished physicist, in an autograph letter, declares—"As regards the name of the instrument, 'Crookes's Radiometer' is the only suitable appellation, expressing at once the merit of the discoverer and the nature of the matter." It is no disparagement to the unimpeachable skill of Herr Geissler to say that the instrument should bear the name of its inventor rather than of its maker.

It is, to say the least, an unfortunate coincidence that the gentleman who has thought fit to employ this novel nomenclature has, with reference to the discovery in question, scarcely shown the candour and courtesy usual in physical and chemical discussions. After the reading of the first paper at the Royal Society Prof. Osborne Reynolds, in a letter to the editor of *Nature*, and in a paper which was read before the Royal Society on June 18, 1875, gave it as his opinion that the results we had obtained were in part due to evaporation and condensation, and that they afforded a direct proof of the truth of the kinetic theory of gases. Both in a letter to *Nature*, and in a lecture delivered before the Physical Society on the 20th of June, we brought forward what we conceived to be reasonable arguments against this supposed explanation. We stated that our impression was that the repulsion caused by radiation was directly due to impact upon the surface of the moving mass, and not secondarily through the intervention of air currents, electricity, or evaporation and condensation, but that we did not wish to insist upon any theory of our own, our object being to ascertain facts, varying the conditions of each experiment, so as to find out what are the necessary and what the accidental accompaniments of the phenomena. By working steadily in this manner, letting each group of experiments point out the direction for the next group, and following up as closely as possible, not only the main line of research, but also the little bye-lanes which often lead to the most valuable results, after a time the facts will group themselves together and tell their own tale. The conditions under which the phenomena invariably occur will give the laws, and the theory will follow without much difficulty.

At the meeting of the British Association in August last, Prof. Reynolds said* "he thought that some energy was given to the moving body which enabled it to propel itself. He did not desire to throw any slight upon the work of Mr. Crookes, *but the latter should not produce facts to subvert preconceived notions of the nature of things*, and deprecate explanations being given in accordance with principles previously well established."

Whether or not in what we have stated above we can fairly be charged with deprecating *explanations* given in accordance with principles previously well established, we leave to the judgment of our readers.

Since our earlier researches we have vastly improved the apparatus, and carried out numerous experiments, the results of which are embodied in three subsequent papers

* *Bristol Daily Post*, September 1, 1875.

54

Repulsion Resulting from Radiation.—W. Crookes.—Presented by M. Th. du Moncel.—For several years I have been pursuing my researches on the repulsive force resulting from radiation transmitted through rarefied gases. The apparatus I used consisted of a torsion balance, in which the beam for carrying the experimental disks is a straw suspended by a very fine glass fibre. Six disks, each differing from each other, are suspended from one end of this beam, and they are balanced at the other end by a suitable counterpoise. A standard candle, placed at a fixed distance from the balance, supplied the radiation, and the displacements produced by this radiation were increased on a graduated scale by a ray of light reflected from a mirror. A screen was so arranged that the light might fall on any disk selected for experiment without the others being affected. Finally, a standard lampblacked disk was placed in the apparatus in order that the results might be compared. All the apparatus was carefully sealed and attached to a mercury pump capable of carrying the exhaustion to any desired point. My experiments have extended over one hundred different substances, and I have measured the effect produced by them, not only under the influence of simple radiation from a luminous source, but also by removing the invisible heat rays by the interposition of a water screen. In this manner I found that each substance exercises a more or less distinct action on the absorption of rays. Thus most white powders powerfully absorb the invisible heat rays, while they are almost without action on the luminous rays.

On the contrary, the black powders powerfully absorb the luminous rays and only slightly absorb the obscure heat rays whatever their intensity may be. The different metals present great differences in their action. Iron, for instance, chiefly absorbs the invisible heat rays, while gold is principally acted on by the luminous rays. The substances I have experimented with may be divided into two classes: 1st. Those whose action is increased by the interposition of water screens with regard to the effect produced on the standard disk; 2nd. Those in which the contrary is the case. Amongst the former may be mentioned copper tungstate, saffranin, precipitated selenium, and copper oxalate; these are more affected by light than by invisible heat. Amongst class 2 may be mentioned chromic oxide, persulphocyanogen, zinc oxide, barium sulphate, and calcium carbonate; these are acted upon more by the ultra-red rays than by the luminous rays. Remarkable effects may be obtained by combining the substances in these two categories on the disk of the radiometer. Thus, if we alternately coat these disks, which we will suppose to be made of pith, with chromic oxide and precipitated selenium, the radiometer will be seen to turn in one direction when it is exposed to the light of a candle, and the contrary way when a water screen is interposed before the luminous source. A similar radiometer, the vanes of which are coated with saffranin and hydrated zinc oxide, does not move at all when it is directly exposed to the flame of a candle, but will be set in motion as soon as a water screen is interposed. In a note which I have had the honour of presenting to the Academy of Sciences I have shown that when the exhaustion of a radiometer is carried beyond a certain limit its sensibility gradually diminishes until it became absolutely null. I have entered more deeply into this question, and have come to the conclusion: 1st. That there is a gradual increase in the sensitiveness of the radiometer until the pressure has attained 50 millionths of an atmosphere (0·038 millim.); 2nd. That beyond this limit to 30 millionths of an atmosphere (0·013 millim.) it remains stationary; 3rd. Further still, it sinks rapidly until at 1 millionth (0·00076 millim.); 4th. That at 0·2 millionth of an atmosphere (0·00015 millim.) the radiometer refuses to turn even when five candles are put near it. To examine the effects of molecular pressure produced directly by heat upon a radiometer I arranged, besides the system of vanes suspended horizontally, a ring of platinum which could be rendered incandescent by an electric current. The vanes were of transparent mica, and were inclined to each other like the sails of a windmill, and above these vanes was a mica disk, which turned on a separate pivot. The normal direction of this disk was naturally inverse to that of the system of vanes. The following are the results I obtained:—

(1.) When the apparatus is full of air at the normal pressure of 760 m.m., and the platinum ring was incandescent, the direction of the rotation of the vanes and disk was *positive*, that is to say, that which would be produced by a current of air coming from the platinum ring: this effect must be attributed to the ascending current of hot air. (2.) At a pressure of 80 millims. the disk did not turn. The vanes turned slowly in the positive direction. (3.) At 19 millims. no movement was produced either by the disk or by the vanes. (4.) At 14 millims. the disk remained stationary, but the vanes began to turn gently in the negative direction, that is to say, in a way inverse to their first direction. (5.) At 1 millim. the disk turned in a continuous manner in the positive direction, whilst the vanes turned rather fast in a negative direction. (6.) At 0·224 millim. the speed of the disk or the vanes was the same, and their rotative movement was the same. Below the pressure the speed of the rotation of the vanes diminished gradually, whilst the speed of the disk increased, and at a pressure of 0·107 millim. the disk turned rapidly in the positive direction, whilst the vanes were motionless. (7.) With a more perfect exhaustion still, at 0·098 millim. a sudden change was seen. The vanes which had been

stationary then began to turn in the positive direction at a speed of 100 revolutions per minute, whilst the disks turned as before, positively, but with less speed. It is probable that the speed of this disk was diminished in consequence of the rapid movement of the vanes in the opposite direction.* (8.) When the exhaustion was carried beyond 0·098 millim. the speed of the two disks and of the vanes increased till it exceeded 600 revolutions per minute, and it did not seem to diminish with the highest rarefaction, which was at 0·0001 millim. According to the most recent determinations the number of molecules contained in a cubic centimetre of air at the ordinary pressure is probably something like 1,000,000,000,000,000,000,000 (one thousand trillions); consequently, at an exhaustion of 0·0001 millim., 100,000,000,000,000 are still left. This number is sufficiently large to justify the hypothesis—That when the molecules are set in vibration by a white-hot platinum wire they are still capable of exercising an enormous mechanical effect.

Comptes Rendus Hebdomadaires des Séances de l'Académie des Sciences, tome lxxxi., No. 2, July 12, 1875.

Magneto-Chemical Phenomena Produced in a Medium of Rarefied Gases in Geissler's Tubes Illuminated by means of Induction Currents.—M. J. Chautard.—(Third part.) In all the simple bodies of the chlorine group, and in all their derivative compounds, gaseous or volatile, which have been examined, the action of the magnet is instantaneous, and is shown—not merely by a change in the tint of the tube—but, above all, by a more complete illumination of the rays which display a wonderful brilliancy, and are sometimes split up. The wavelengths of each ray will form the subject of a future communication. The substances examined, beside chlorine, bromine, and iodine, are the chloride, bromide, and fluoride of silicium, the fluoride of boron, hydrochloric acid, antimony chloride, bismuth chloride, mercurous chloride, and stannous and stannic chlorides. The lights of sulphur and of selenium are completely extinguished in the moment when the magnet is set in action, and it is the same with that of tubes of chlorine, bromine, and iodine if the strength of the coil is suitable. The lustre of the light of oxygen, always pale, undergoes no very sensible change. It is the same with the compounds of carbon, such as carbonic acid and oxide, proto- and bi-carbide of hydrogen. The fine bands of the nitrogen spectrum are merely modified in the red and orange portion. These colours are almost entirely extinguished, or, at least, are replaced by a very uniform tint, in which there is no trace of "chanelling." The bands of the more refrangible portion remain unaltered. The rays of hydrogen preserve the same appearance; yet, on employing an electro-magnet of sufficient strength, we see appear at the moment when it is set in action a very brilliant yellow ray, which is merely that of sodium derived from the glass. This ray vanishes as soon as the circuit is broken, and reappears if the magnetisation is resumed. Protochloride of tin, dry and crystalline, but bihydrated, presents a most remarkable phenomenon of dissociation under the influence of the magnet. In its normal state the spectrum is pale, and presents some of the green rays of chlorine; but as the magnet is set in action we see two of the characteristic rays of hydrogen, the red and the blue, which remain as long as the magnetisation lasts, and disappears when it ceases.

In connection with the recent rapid progress in electric lighting it is interesting to recall the fact that Otto Von Guericke (1602-1686), burgomaster of Magdeburg, and inventor of the air-pump, was the first who produced light by electricity. He did so by simply pressing his hands against a globe of sulphur, which was set in rapid rotation about one of its diameters. The effect he describes as being similar to the glow of sugar when bruised in the dark. The spark was obtained more distinctly a short time afterwards by Dr. Wall, by rubbing a piece of amber with a woollen cloth. He, with others, believed that in such cases the light was the cause of the electric state. The advance from these germinal observations to the electric light as now used—e.g., in our lighthouses—is remarkable.

REPULSION RESULTING FROM RADIATION.

Apr 78

By W. Crookes.

[Presented to the French Academy by M. Th. du Moncel.]

For several years I have been pursuing my researches on the repulsive force resulting from radiation transmitted through rarefied gases. The apparatus I used consisted of a torsion balance, in which the beam for carrying the experimental disks is a straw suspended by a very fine glass fiber. Six disks, each differing from each other, are suspended from one end of this beam, and they are balanced at the other end by a suitable counterpoise. A standard candle, placed at a fixed distance from the balance, supplied the radiation, and the displacements produced by this radiation were increased on a graduated scale by a ray of light reflected from a mirror. A screen was so arranged that the light might fall on any disk selected for experiment without the others being affected. Finally, a standard lampblacked disk was placed in the apparatus in order that the results might be compared. All the apparatus was carefully sealed and attached to a mercury pump capable of carrying the exhaustion to any desired point. My experiments have extended over one hundred different substances, and I have measured the effect produced by them, not only under the influence of simple radiation from a luminous source, but also by removing the invisible heat rays by the interposition of a water-screen. In this manner I found that each substance exercises a more or less distinct action on the absorption of rays. Thus most white powders powerfully absorb the invisible heat rays, while they are almost without action on the luminous rays. On the contrary, the black powders powerfully absorb the luminous rays and only slightly absorb the obscure heat rays, whatever their intensity may be. The different metals present great differences in their action. Iron, for instance, chiefly absorbs the invisible heat rays, while gold is principally acted on by the luminous rays. The substances I have experimented with may be divided into two classes: 1st. Those whose action is increased by the interposition of water-screens with regard to the effect produced on the standard disk; 2d. Those in which the contrary is the case. Among the former may be mentioned copper tungstate, saffranin, precipitated selenium, and copper oxalate; these are more affected by light than by invisible heat. Among class 2 may be mentioned chromic oxide, persulphocyanogen, zinc oxide, barium sulphate, and calcium carbonate; these are acted upon more by the ultra-red rays than by the luminous rays. Remarkable effects may be obtained by combining the substances in these two categories on the disk of the radiometer. Thus, if we alternately coat these disks, which we will suppose to be made of pith, with chromic oxide and precipitated selenium, the radiometer will be seen to turn in one direction when it is exposed to the light of a candle, and the contrary way when a water screen is interposed before the luminous source. A similar radiometer, the vanes of which are coated with saffranin and hydrated zinc oxide, does not move at all when it is directly exposed to the flame of a candle, but will be set in motion as soon as a water-screen is interposed. In a note which I have had the honor of presenting to the Academy of Sciences, I have shown that when the exhaustion of a radiometer is carried beyond a certain limit its sensibility gradually diminishes until it becomes absolutely null. I have entered more deeply into this question, and have come to the conclusion: 1st. That there is a gradual increase in the sensitiveness of the radiometer until the pressure has attained 50 millionths of an atmosphere (0·038 millim.); 2d. That beyond this limit to 30 millionths of an atmosphere (0·013 millim.) it remains stationary; 3d. Further still, it sinks rapidly until at 1 millionth (0·00076 millim.); 4th. That at 0·2 millionth of an atmosphere (0·00015 millim.) the radiometer refuses to turn even when five candles are put near it. To examine the effects of molecular pressure produced directly by heat upon a radiometer I arranged, besides the system of vanes suspended horizontally, a ring of platinum which could be rendered incandescent by an electric current. The vanes were of transparent mica, and were inclined to each other like the sails of a windmill, and above these vanes was a mica disk, which turned on a separate pivot. The normal direction of this disk was naturally inverse to that of the system of vanes. The following are the results I obtained: (1.) When the apparatus is full of air at the normal pressure of 760 m.m., and the platinum ring was incandescent, the direction of the rotation of the vanes and disk was *positive*, that is to say, that which would be produced by a current of air coming from the platinum ring: this effect must be attributed to the ascending current of hot air. (2.) At a pressure of 80 millims. the disk did not turn. The vanes turned slowly in the positive direction. (3.) At 19 millims. no movement was produced either by the disk or by the vanes. (4.) At 14 millims. the disk remained stationary, but the vanes began to turn gently in the negative direction, that is to say, in a way inverse to their first direction. (5.) At 1 millim. the disk turned in a continuous manner in the positive direction, while the vanes turned rather fast in a negative direction. (6.) At 0·224 millim. the speed of the disk or the vanes was the same, and their rotative movement was the same. Below the pressure the speed of the rotation of the vanes diminished gradually, while the speed of the disk increased, and at a pressure of 0·107 millim. the disk turned rapidly in the positive direction, while the vanes were motionless. (7.) With a more perfect exhaustion still, at 0·098 millim. a sudden change was seen. The vanes which had been stationary then began to turn in the positive direction at a speed of 100 revolutions per minute, while the disks turned as before, positively, but with less speed. It is probable that the speed of this disk was diminished in consequence of the rapid movement of the vanes in the opposite direction.* (8.) When the exhaustion was carried beyond 0·098 millim. the speed of the two disks and of the vanes increased till it exceeded 600 revolutions per minute, and it did not seem to diminish with the highest rarefaction, which was at 0·0001 millim. According to the most recent determinations the number of molecules contained in a cubic centimeter of air at the ordinary pressure is probably something like 1,000,000,000,000,000,000,000 (one thousand trillions); consequently, at an exhaustion of 0·0001 millim., 100,000,000,000,000 are still left. This number is sufficiently large to justify the hypothesis that when the molecules are set in vibration by a white-hot platinum wire they are still capable of exercising an enormous mechanical effect.

A NEW MOTIVE POWER.

The mechanical action of the radiation of light and heat, although noticed by several observers during the past half-century, has not until recently been made the subject of careful study and experiment. To Dr. William Crookes, of London, the distinguished chemist, belongs the honor of first [illegible]ting by delicate mechanical contr[illegible]ces [illegible]istence of a power in radiant light [illegible] opens up new fields for thought and investigation. This discovery and the experiments of Dr. Crookes have produced an amount of interest in the world of science but little [illegible] awakened by the splendid researche[illegible] and Kirchhoff, wi[illegible] spectroscop[illegible]. The experiments of Dr. Crookes beg[illegible] three years ago, and the first paper upon the subject w[illegible]ted to the Royal Society in May, 1873, but it was not until 1875 that the new-found fact, the mechanical effect of radiation in a vacuum, was announced to the world.

The researches of Dr. Crookes are regarded as so new and wonderful that the President of the Mathem[illegible]ical and Physical Section of the British Association last summer stated that "they were among the most interesting in the whole range of physical science." He claims to [illegible] proved that there is exerted by the sun's rays a direct mechanical action; that when light bodies are delicately poised in a vacuum under [illegible] adjustments, they are moved or *repelled* [illegible] of light, natural or artificial. This [illegible] to be independ[illegible] air, and [illegible] radiant [illegible] appar[illegible] invented by Dr. [illegible] establish this view has been quite [illegible] produced in this country, and Profes[illegible] [illegible] periment[illegible] with the "radiomet[illegible] the results of which are presented i[illegible] interes[illegible] published in the *Adv[illegible]er*, of [illegible] April 3d. The radiometer [illegible] described by Dr. Crookes has been made in this country, so far as we know, only by Mr. Demuth, of Cambridge, a very skillful glass-blower. After Mr. Demuth succeeded in making the delicate little instrument, and had produced a dozen or two which have been widely distributed, he was taken sick of pneumonia, and died. [illegible] lived, undoubtedly he would have succeeded in making instruments much more perfect than any of those now in the hands of experimenters. Mr. Demuth's radiometer consists of a little wheel, which revolves inside of a glass bulb from which the air has been exhausted. When placed in the sunlight, or near a gas-light or candle, the little arms, to which are [illegible] thin disks of mica, having one surface blackened, revolve with great rapidity upon the delicate needle-point forming the axis on which they are poised.

Professor Cooke differs from Dr. Crookes in his interpretation of the cause of the movements produced, and attributes them to molecular action in the attenuated atmosphere within the bulb. In his view it is the action of heat rather than of light, and in this he is sustained by the views of Professor Dewar, of Scotland, Herr Neesen, of Germany and several other experimenters of note. Professor Cooke's paper, to which allusion has been made, is exceedingly interesting, and we regret that we have not space to copy it entire.

From some perhaps imperfect experiments with the radiometer, we are led to conclude that the movements occur only under the combined action of light and heat. We do not find that dark heat, like that from st[illegible] or hot air, produces the rep[illegible] or movements in a vacuum near perfection. Neither does light, when the calorific rays are cut off. Dr. Crookes's apparatus is undoubtedly much more perfect and sensitive than any which has been produced here. If it were possible to obtain an absolute vacuum inside the radiometer bulb, the difference of views among scientific men as regards the cause of the motion could be settled at once. If Professor Cooke's views are correct, the disk would be motionless; if, on the other hand, the motion is due to light-energy alone, the movements would increase in velocity, and the discoverer's views would be sustained. Professor Dewar's vacuum, like that obtained by Dr. Crookes, was nearly perf[illegible] — so perfect as to [illegible] passage of the induction spark. After the pump refused to reduce the tension of the gas, the residue was removed, and the vacuum further perfected by the absorbent power of charcoal. But all this care and labor fell short of producing a *perfect* vacuum, and wi[illegible] this the decisive experiment cannot be [illegible]. The results thus far [illegible] Dr. Crookes's patient labor, ingenuity, and scientific skill are worthy of the abundant applause he has received. The medal of the Royal Society was bestowed for the discovery, the highest honor which the most learned body in England can confer.

It is a curious circumstance that this honor is conferred upon one who a short time ago presented papers to the Royal Society describing impostant experiments and discoveries in another class of phenomena, which were refused reception and even examination by the *savants*. Dr. Crookes devoted *three years* of careful study and experiment to the class of phenomena called "spiritual," and he brought to the labor the same indefatigable perseverance, the same skill in devising mechanical appliances, the same scientific learning, the same clear, cool, analytical powers of mind, displayed in his researches upon the mechanical action of light, but his labors were ridiculed and rejected without examination. We have carefully read Dr. Crookes's papers upon the "psychic force," or "spiritualism," or whatever the class of phenomena may be called, which have appeared in the London *Quarterly Journal of Science*, and we unhesitatingly say that in our view they do not rightfully belong to the class of "rejected papers" to which they

whole of it in the form of carbonate, it is perfectly useless for them to think that that paint can possess a covering power to be compared with that of a genuine article.

ANNUAL CONVERSAZIONE OF THE ROYAL SOCIETY, LONDON.

The recent Conversazione of the Royal Society, held at Burlington House, well kept up the high character of the now long series of receptions which the Royal Society has given to its friends. The libraries were literally filled with objects of high scientific interest, and the period of three hours, during which the conversazione lasted, were all too short for the study which they deserved, especially as on such occasions that study must necessarily be so largely interrupted by friendly greetings and conversation.

RADIOMETERS.

Mr. Crookes, F.R.S., occupying his usual corner of the librarian's room, exhibited a splendid collection of radiometers and specimens of his new modification of them, to which he has given the name of the Otheoscope, or propulsion indicator. This instrument differs from the radiometer in the fact that the propelling power is caused by the radiation from blackened stationary disks or vanes fixed at a suitable angle in the neighborhood of the movable fly and within the exhausted envelope. The vanes of the fly, unlike those of the radiometer, are alike on both sides, and the action is precisely like what it would be if the fixed vanes were emitting jets of air and blowing the fly round after the manner either of a Robinson's anemometer or of a smoke-jack. In one of these instruments a four-armed fly with vanes made of mica rendered opaque by roasting is supported on a central pivot like the fly of a radiometer, and within the glass envelope rigidly attached to its sides are three vertical plates of clear mica set at an angle somewhat oblique to the axis. When a candle is approached the molecular disturbance caused by radiation from the oblique plates impinge on the fly and causes it to rotate. In another form a horizontal disk of roasted mica is balanced at its center on a vertical point, and below it is a fixed circle of inclined aluminum vanes of the form of the wheel of a smoke-jack. Upon approaching a candle to this instrument the upper disk moves with great velocity, being driven by the molecular forces caused by radiation acting obliquely to the under surface of the upper disk. Mr. Crookes also showed an instrument which is the converse of the last. In this case the fly is composed of inclined planes of aluminum similar to the fixed vanes in the instrument last described, and below it is fixed a blackened disk of mica. When a source of radiation is approached molecular disturbance takes place due to the radiation from this disk, but as the angles of incidence of the vanes of the fly are inclined to the direction of this molecular disturbance, motion is given to the fly and it rotates at great speed.

Of radiometers Mr. Crookes showed some very interesting specimens, illustrating very remarkably the theory of the radiometer propounded by Dr. Johnstone Stoney. In one example a radiometer of the usual construction, that is to say, having its vanes blackened on one side only, has attached at a short distance from and parallel to the black surface of each vane a large disk of clear mica. When a candle is brought near this radiometer the fly rotates in the abnormal direction, that is to say, with its black surfaces toward the light. This reversal of motion is caused by the reflection, [illegible]on the clear mica plates, of the molecular disturbance set [illegible] by radiation from the black surface. In corroboration of [illegible]is hypothesis Mr. Crookes showed another instrument in [illegible]hich each vane carried two large disks, one on each side. [illegible] this case the molecular disturbance, prevented from being [illegible]flected backwards by the second equal-sized disk, can only [illegible]cape in planes symmetrical with the diameters of the fly, [illegible]d consequently no motion is produced on the approach of [illegible] lamp.

In another new form of experimental radiometer the vanes [illegible] the fly are of aluminum, bright on both sides and cup-[illegible]aped, similar to those in Dr. Robinson's anemometer, but [illegible]t so deep. Unlike the anemometer, however, the vanes [illegible]tate with the concave surface forward. The radiation [illegible]om a standard candle placed 3½ in. from this instrument, [illegible]d falling equally on both convex and concave surfaces, [illegible]used the vanes to rotate at a speed of about 18 revolutions [illegible]er minute. When a screen was placed between the candle [illegible]d the instrument in such a position as to allow it to shine [illegible]ly on the convex surfaces, the vanes rotated in the same [illegible]irection as before, but at the reduced speed of 8 revolutions [illegible]er minute; the screen was then shifted so as to screen the [illegible]onvex surfaces, allowing the radiation to fall only on the [illegible]oncave surface, the rotation continued as before, but at a [illegible]peed of 8¼ revolutions per minute. Mr. Crookes arranged [illegible]his experiment to show that the repelling influence of radiation on the convex surface is about equal to its attracting influence on the concave surface, and that the double velocity at which the vanes move when both surfaces are exposed to the radiating force is the result of the sum of these two influences. As a sequel to this experiment, Mr. Crookes showed an interesting pair of radiometers similar in construction to that last described, but having in one instrument the concave surface blackened, and in the other the convex. In the former the usual action of radiation is reversed, the bright convex surface being repelled and the black concave surface attracted. In the latter, as might be expected from a consideration of the two experiments, the rotation was in the usual direction and very rapid. In the former the two conditions of the vanes, viz., the curvature of surface and the blackening of one side, are acting against one another, the surface form having the large influence; and in the latter the two conditions by which the vanes are rendered sensitive to the mechanical influence of radiation or acting together, and the speed is consequently increased.

All these instruments are marvels of constructive skill, and have been made by Mr. C. H. Gimingham, who has been associated with Mr. Crookes in this research from the first. Two instruments especially ought to be mentioned as examples of extraordinary delicacy of manipulation. One was an eight-armed radiometer rotating at a great velocity upon a horizontal axis, which was supported by two glass cups so delicately adjusted by fusion of their glass supports as to nip the fine needle-points of the horizontal spindle, so as to prevent the latter dropping from its central position, and yet so free from friction that the light of a single candle caused it to "run away." The other instrument consisted, first, of a radiometer having four large rectangular vanes; each of these vanes carried above it a secondary, tiny four-armed radiometer, which consequently had a sort of "lunar" motion, rotating on its own pivot, which in its turn was carried round by the larger radiometer. Above the central fly was again

ELECTRIC DISCHARGE IN TUBES CONTAINING RAREFIED GASES.

July 78

By MM. Warren de la Rue and Hugo W. Müller.

The discharge in a tube of rarefied gas does not differ from that which takes place in air or other gases at the atmospheric pressure. It is not a current in the ordinary sense of the term, but a disruptive discharge, the gaseous molecules effecting a transport of electrization. The gases probably receive two impulsions in opposite directions, that from the negative electrode being the more continuous. There are sometimes formed metallic spots upon the tubes, which leave a permanent trace of the intervals comprised between the strata.

59

ELECTRIC DISCHARGE IN GASES[1]

II.

THE form of point most favourable to the production of the arc has been minutely investigated by the authors. By turning wires in a lathe to various outlines they arrived experimentally at the best point; this was then placed under the microscope and drawn by means of the camera lucida; from the study of the drawing it was ascertained that the longest spark was procured when the point assumed a form resembling a paraboloid; the curved out

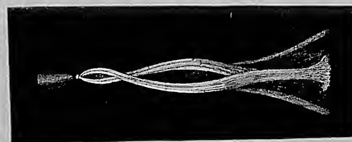

Fig. 8.—"Streamers."

line, which corresponded to that found experimentally, was one in which each succeeding ordinate was in the ratio of the square root of the odd numbers 1, 3, 5, &c., the sectional areas being consequently in the ratio of the odd numbers.

The curves in the diagram (p. 528) show the distances at which, with a given potential, the arc is formed between such a point and a disc, and between two such points respectively. The results recorded in the case of the point and disc are those obtained by electrifying the point to the sign (positive or negative) which gave the greatest length; for it was found that with low potentials the distance at

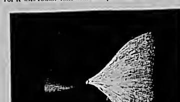

Fig. 9.—"Glow."

which the arc forms is greater when the point is *negative*, that between 3,000 and 5,000 volts it is the same whether the point be positive or negative, but that with potentials higher than 5,000 volts it is greater when the point is *positive*.

The actual formation of the arc, when a point and disc or two points are employed as terminals, is preceded by a luminous discharge (streamers and glow), presenting phenomena of an interesting character; an extremely minute quantity of electricity passes as compared to that

Fig. 10.—"Streamers and Glow."

when the arc is formed, but still it is sufficient when

[1] Continued from p. 528.

Geissler's Tubes.

The tubes manufactured by Geissler in Bonn, Germany, for showing the flow of electricity in rarefied air, gases, and vapors, have lately obtained a regular foothold in all collections of philosophical apparatus and the experimental lectures in physics. They consist simply of tubes of thin glass of various forms, sealed at the ends, and perforated there with platinum wires, soldered in the glass. There is no metal better adapted for this purpose, because its expansion by heat is very nearly equal to that of glass, so that in heating and cooling there is no unequal expansion and contraction, and therefore the main cause of the cracking of the glass in the process of manufacturing the tubes is avoided.

Fig. 1 represents three different forms of these tubes;

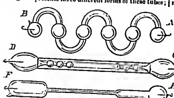

Fig. 1.—Geissler's Tubes.

E F is the most common. In this form the glass is contracted in the middle, so as to compel the electrical discharge to pass through a narrow space and thus be concentrated or condensed to a very luminous narrow line, especially adapted for observation by the spectroscope. C D is a more complex arrangement, in which small perforated globes of uranium glass have been inserted into the tube; this glass becomes very florescent by the electrical discharge, and adds greatly to the beauty of the luminous phenomenon. A B is still another form, in which a series of glass globes are connected by means of semi-circular tubes, which gives a very pretty appearance to the luminous electric current. The figures show plainly the platinum wires at the extremities, and it is only necessary to connect the projecting ends of one of these wires with a source of electricity and the other with the ground, to observe the brilliant phenomena referred to.

The pressure of the air, gas, or vapor in these tubes is very small, not exceeding one-fiftieth of an inch, and this is obtained by first exhausting the air with a good air-pump, then admitting the gas or vapor, and lastly exhausting again until the required low pressure is obtained. The latter is a very delicate point, because when the exhaustion is insufficient, the electric current receives too much resistance, and does not pass freely enough, while when on the contrary an absolute exhaustion of all gas or vapor is accomplished, the inner space of the tube becomes an absolute non-conductor and absolutely refuses the passage of any electricity, however powerful it may be. In fact, the experiments with these tubes have revealed to us the important and startling truth (referred to in another part of this number) that the vacuum is an absolute non-conductor.

Sometimes the discharge of the electric current through the rarefied gas or vapor, shows cross striæ of different shapes, colors, and lusters, depending upon the nature of the gas, the dimensions of the tube, and the degree of rarefaction.

Now when A B, Fig. 1, is filled with rarefied hydrogen gas, the striæ will be white in the bulb and red in the narrow tubes. Carbonic acid will show a greenish stratification; nitrogen, an orange-yellow; while the spectroscope peculiar lines in each gas or vapor characteristic of its nature, and giving the direct means to recognize one from the other. It is also to be remarked that the lines revealed by the spectroscope differ for different temperatures, and that those produced by electric currents coincide with those obtained by the highest possible temperature, very different from the lower degree of heat obtained by a simple flame.

Fig. 2 represents a large set of Geissler tubes attached to a rotating disk. The stand A supports a wooden disk B, revolved by a handle; a string running over its circumference runs also over a small disk—not seen in the figure—and communicates to this and to its axis a very rapid revolving motion. This axis carries the triangular disk to which the tubes are attached, while the electric current passes from one to the other, and at the end is connected with two distinct and mutually isolated parts of the axis, so that while the disk is in rapid rotation the electric current may be as easily passed through the tubes as when the disk is in repose. This communication is made from the stand D F by successive sparks, which intermittent illumination, combined with the rotatory movement, makes this one of the most interesting and showy exhibi-

ON THE THERMAL PHENOMENA PRODUCED BY THE PASSAGE OF ELECTRICITY THROUGH RAREFIED GASES[1] 1878

A PORTION of the experiments described in this paper were made before the publication of Wiedemann's experiments on the same subject. The authors state that if they had known of the work of the German physicist they would probably not have undertaken the investigation, but they have continued the experiments and think them worthy of description as the methods employed differ from those of Wiedemann.

The apparatus used consisted of ordinary Geissler tubes, the electrodes being in wide tubes connected by a narrow one. A large Ruhmkorff's coil with a secondary wire 100,000 metres in length was set in action by two large Bunsen cells, and the current was made and broken by a Foucault's interrupter. In order to measure the induced current a reflecting galvanometer was employed, being placed at such a distance from the coil that the effect of the electro-magnet on the needle was very small; this slight deviation was, however, applied as a correction in all the readings. It was first proved that the current induced on completing the primary circuit was incapable of passing through the Geissler tube, for the galvanometer needle was equally deflected whether placed in the secondary circuit or not, indicating that the movement of the needle was due solely to the direct action of the magnet of the coil; on the contrary, when the primary circuit was broken, a considerable deflection of the needle occurred when the galvanometer was in the secondary circuit, and a slight one, but in the opposite direction, when the needle was influenced by the magnetism of the coil alone.

Tubes containing chlorine, carbonic anhydride, and hydrogen, were employed in the experiments, the electrodes being soldered to the wires from the coil by means of Wood's fusible alloy. The narrow part of the tube was placed in a copper cylinder containing water, or preferably mercury, in which a delicate thermometer was immersed, the deflection of the galvanometer was read every thirty seconds, and the thermometer every minute. When the current indicated by the galvanometer was greatest the increase of temperature was most rapid, but the important fact shown by these experiments is that in every case the rise of temperature divided by the deflection is a constant. Unfortunately the different constants are not comparable, as the experiments were not made with the same tube containing the different gases at known pressures, but with different tubes of nearly the same sizes; but the pressures of the gases are not given.

Some experiments were undertaken to determine the heating effects in the neighbourhood of the electrodes. For this purpose the upper end of a Geissler tube containing chlorine was placed in the calorimeter, the latter surrounding the part of the tube containing the platinum wire. When the electrode was negative about eight times more heat was developed than when it was positive. As the quantity of heat produced when the electrode was positive was very small the relation between the deflection of the galvanometer and the rise of temperature was not so regular in the different experiments as in the other case; and when the electrode was negative it was observed that the quantity of heat increased a little more rapidly than the deflection. More accurate results were obtained by immersing the lower end of the tube in the calorimeter; under these circumstances the quantity of heat collected when the electrode was negative was 22·8 times as great as in the experiments in which it was positive, and while the deflection of the galvanometer varied from 100 to 640, the rise of temperature divided by the deflections increased from 100 to 120 only.

It being suspected that the different effects at the two electrodes might be due to a cause similar to the Peltier effect in solid conductors, an attempt was made to discover if the positive electrode is cooled during the passage of the electricity. There appeared to be a very slight diminution of temperature at the commencement of the experiment, but it was soon masked by the conduction of heat from other parts of the tube.

The calorimeter was next placed on the wide part of the Geissler tube, but not surrounding the electrode, which was 16·5 mm. from the calorimeter. In this case, also, a larger quantity of heat was developed near the negative electrode than near the positive, but the ratio was only 4·9. When a portion of the narrow part of the tube was placed in the calorimeter, that near the negative electrode was slightly more heated than the other portion. When a tube containing hydrogen was used similar results were obtained, but the difference between the quantities of heat at the two ends was very much less than in the case of chlorine.

The next series of experiments was made to determine the effect of different diameters of tube. For this purpose a U-tube containing air of the pressure of two mm. was used, one limb of the tube having a sectional area of 36·3 square mm., the other 12·6 square mm., both limbs being surrounded by calorimeters. The quantity of heat developed in the narrow tube was only very slightly greater than in the other, the ratio being about 1·1. By using another tube with the areas of 116·9 square mm. and 4·5 a similar result was found, but in this case the ratio was not greater than 1·2.

ON THE ILLUMINATION OF LINES OF MOLECULAR PRESSURE, AND THE TRAJECTORY OF MOLECULES.

Jan 79

By WILLIAM CROOKES, F.R.S., V.P.C.S.

Induction Spark through Rarefied Gases. Dark Space round the Negative Pole.

THE author has examined the dark space which appears round the negative pole of an ordinary vacuum tube when the spark from an induction coil is passed through it. He describes many experiments with different kinds of poles, a varying intensity of spark, and different gases, and arrives at the following propositions.

Illumination of Lines of Molecular Pressure.

a. Setting up an intense molecular vibration in a disc of metal by electrical means causes a molecular disturbance to proceed from the surface of the disc to the surrounding gas. When the gas is dense, the disturbance only extends a short distance from the metal, and, as rarefaction proceeds, the layer of molecular disturbance increases in thickness. In air at a pressure of ·078 millimetres this molecular disturbance extends for at least 8 millimetres from the surface of the disc, forming an oblate spheroid round it.

b. The diameter of this dark space varies with the exhaustion; with the kind of gas in which it is produced; with the temperature of the negative pole; and, in a slight degree, with the intensity of the spark. For the same degree of exhaustion it is greatest in hydrogen and least in carbonic acid, as compared with air.

c. The shape and size of this dark space do not vary with the distance separating the poles; or, except very slightly, with alteration of battery power; or with intensity of spark. When the power is great the brilliancy of the rest of the tube overpowers the space, and renders it difficult to observe; but, on careful scrutiny, it is seen to be there unchanged in size. With a very faint spark the space is still present, unaltered in dimensions, although scarcely visible; and if the power is still further diminished, it fades out altogether, without change of shape.

The author describes numerous experiments, devised to ascertain if this visible layer of molecular disturbance is identical with the invisible layer of molecular pressure or stress, the investigation of which has occupied him for some years.

The Electrical Radiometer.

"One of these experiments is as follows:—An ordinary radiometer is made, with aluminium discs for vanes, each disc having a film of mica close to one side. Instead of a glass cup, the fly is supported by a hard steel cup, and the needle point on which it works is connected by means of a wire with a platinum terminal sealed into the glass. At the top of the radiometer bulb a second terminal is sealed in. The radiometer can therefore be connected with an induction coil, and the moveable fly be made the negative pole.

Passing over the phenomena observed at low exhaustions, it is found that, when connected with the coil, a halo of a velvety violet light forms on the metallic side of the vanes, the mica side remaining dark throughout these experiments. As the pressure diminishes, a dark space is seen to separate the violet halo from the metal. At a pressure of half a millimetre this dark space extends to the glass, and positive rotation commences.

On continuing the exhaustion, the dark space further widens out and appears to flatten itself against the glass, the rotation now being very rapid.

When aluminium cups are used, instead of discs backed with mica, for the vanes of a radiometer, similar appearances are seen. The velvety violet halo forms over each side of the cup. On increasing the exhaustion the dark space widens out, retaining as much as possible the shape of the cup. The bright margin to the dark space becomes concentrated at the concave side of the cup to a luminous focus, and widens out at the convex side. On further exhaustion, the dark space on the convex side touches the glass, when positive rotation commences, becoming very rapid as the dark space further increases in size, and becomes flattened against the glass.

Convergence of Molecular Rays to a Focus.

The subject next investigated is the convergence of the lines of force to a focus, as observed with the aluminium cup. As this could not be investigated when in rapid rotation, an instrument was made, having the cup-shaped negative pole fixed, instead of moveable. On exhausting, the convergence of the lines of force to a focus at the concave side was well observed. When the dark space is very much larger than the cup, it forms an irregular ellipsoid drawn in towards the focal point. Inside the luminous boundary a focus of dark violet light can be seen converging, and as the rays diverge on the other side of the focus they can be seen spreading beyond the margin of the dark space; the whole appearance is strikingly similar to the rays of the sun reflected from a concave mirror through a foggy atmosphere.

Green Phosphorescent Light of Molecular Impact.

At very high exhaustions the dark space becomes so large that it fills the tube. Careful scrutiny still shows the presence of the dark violet focus, and the part of the glass receiving the rays diverging from this focus shows a sharply defined spot of greenish yellow light. On still further exhaustion, and especially if the cup is made positive, the whole bulb becomes beautifully illuminated with greenish yellow phosphorescent light.

This greenish yellow phosphorescence, characteristic of high exhaustions, is frequently spoken of in the paper. It must be remembered, however, that the particular colour is due to the special kind of soft German glass used. Other kinds of glass phosphoresce of a different colour. The phosphorescence only takes place under the influence of the negative pole. At an exhaustion of four millionths of an atmosphere,* no light other than this is seen in the apparatus. At ·9 M the phosphorescence is about at its maximum. When the exhaustion reaches ·15 M the spark has a

* M signifies the millionth of an atmosphere.

difficulty in passing, and the green light only appears occasionally in flashes. At ·06 M the vacuum is almost non-conductive, and a spark can only be forced through by increasing the intensity of the coil, and well insulating the tube and wires leading to it. Beyond that exhaustion nothing has been observed.

Focus of Molecular Force.

In an apparatus specially constructed for observing the position of the focus, the author found that the focal point of the green phosphorescent light was at the centre of curvature, showing that the molecules causing it are projected in a direction normal to the surface of the pole. Before reaching the best exhaustion for the green light, another focus of blue-violet light is observed; this varies in position, getting further from the pole as the exhaustion increases. In the apparatus described, at an exhaustion of 19·3 M these two foci are seen simultaneously, the green being at the centre of curvature, whilst the blue focus is nearly twice the distance off.

Nature of the Green Phosphorescent Light.

The author adduces the following characteristics of the green phosphorescent light, distinguishing it from the ordinary light observed in vacuum-tubes at lower exhaustions:—

a The green focus cannot be seen in the space of the tube, but only where the projection causing it strikes the glass.

b The position of the positive pole in the tube makes scarcely any difference to the direction and intensity of the lines of force which produce the green light. The positive pole may be placed in the tube either at the extremity opposite the negative pole, it may be below it, or by its side.

c The spectrum of the green light is a continuous one, most of the red and the higher blue rays being absent; whilst the spectrum of the light observed in the tube at lower exhaustions is characteristic of the residual gas. No difference can be detected by spectrum examination in the green light, whether the gas whose residue it is has been nitrogen, hydrogen, or carbonic acid.

d The green phosphoresence commences at a different exhaustion in different gases.

e Viscosity of a gas is almost as persistent a characteristic of individuality as its spectrum appearance. The author refers to a preliminary note and a diagram* of the variation of viscosity of air, hydrogen, and other gases at exhaustions between 240 M and ·1 M. From these and other unpublished results, the author finds that the viscosity of a gas suffers very little diminution between atmospheric pressure and an exhaustion at which the green phosphorescence can be detected. When, however, the spectral and other characteristics of the gas begin to disappear, the viscosity also commences to decline, and at an exhaustion at which the green phosphorescence is most brilliant, the viscosity has rapidly sunk to an insignificant amount.

f. The green phosphorescence will not turn a corner in the slightest degree, but radiates from the negative pole in straight lines, casting strong and sharply defined shadows of anything which happens to be in its path. On the other hand, the ordinary luminous phenomena of vacuum tubes will pass along any amount of curves and angles.

Projection of Molecular Shadows.

The author next proceeds to examine the phenomena of shadows cast by the green light. The best and sharpest shadows are cast by flat discs and not by narrow pointed poles; no green light whatever is seen in the shadow, however thin or whatever substance be the material casting it.

From these and other experiments, fully described in the paper, the author ventures to advance the theory that the induction spark actually illuminates the lines of molecular pressure caused by the electrical excitement of the negative pole. The thickness of the dark space is the measure of the mean length of the path between successive collisions of the molecules. The extra velocity with which the molecules rebound from the excited negative pole keep back the more slowly moving molecules which are advancing towards the pole. The fight occurs at the boundary of the dark space, where the luminous margin bears witness to the energy of the collisions of the molecules.

When the exhaustion is sufficiently high for the mean length of path between successive collisions to be greater than the distance between the fly and the glass, the swiftly moving rebounding molecules spend their force, in part or in whole, on the sides of the vessel, and the production of light is the consequence of this sudden arrest of velocity. The light actually proceeds from the glass, and is caused by fluorescence or phosphorescence on its surface. No light is caused by a mica or quartz screen, and the more fluorescent the material the better the luminosity. The author considers that the greenish yellow light is caused by the direct impact of the molecules on the surface of the glass. The shadows are not optical, but are molecular shadows, only they are revealed by an ordinary illuminating effect. The sharpness of the shadow when projected from a wide pole proves them to be molecular.

Phosphorescence of Thin Films.

An experiment is next described in which a film of uranium glass, sufficiently thin to show colours of thin plates, is placed in front of a thick plate of the same glass; the whole being enclosed in a tube with terminals, and exhausted to a few millionths of an atmosphere. With this apparatus the following observations are recorded:—

a. The uranium film, being next to the negative pole, casts a strong shadow on the plate.

b. On making contact with the coil, the thin film flashes out suddenly all over its surface with a yellowish phosphorescence, which, however, instantly disappears. The uncovered part of the plate does not become phosphorescent quite suddenly, but the phosphorescence is permanent as long as the coil is kept at work.

c. With an excessively faint spark the film remains more luminous than the plate, but on making the spark more intense, the luminosity of the film sinks and that of the uncovered part of the plate increases.

d. If a single intense spark be suddenly sent through the tube, the film becomes very luminous whilst the plate remains dark.

These experiments are conclusive against the phosphorescence being caused by the radiation of phosphorogenic ultra-violet light, from a thin layer of arrested molecules at the surface of the glass, for were this the cause, the film could under no circumstances be superior to the plate.

The momentary phosphorescence of the film, and its rapid fading out, prove more than this. The molecular bombardment is too much for the thin film. It responds to it at first, but immediately gets heated by the impacts, and then ceases to be luminous. The plate, however, being thick, stands the hammering without getting hot enough to lose its power of phosphorescing.

* "Proc. Roy. Soc.," Nov. 16, 1876, vol. xxv., p. 305.

Mechanical Action of Projected Molecules.

It was noticed that when the coil was first turned on, the thin film was driven back at the moment of becoming phosphorescent, showing that an actual material blow was given by the molecules. Experiments are next described in which this mechanical action is rendered more evident. A small rotating fly, capable of being moved about in any part of an exhausted bulb, is used as an indicator, and by appropriate means the molecular shadow of an aluminium plate is projected along the bulb. When entirely in, or entirely out of the shadow, the indicator scarcely moved, but when immersed so that one-half was exposed to molecular impact the fly rotated with extreme velocity.

Magnetic Deflection of Lines of Molecular Force.

With this apparatus another phenomenon was investigated. It is found that the stream of molecules, whose impact on the glass causes the evolution of light, is very sensitive to magnetic influence, and by bringing one pole of an electro-magnet or even of a small permanent magnet near, the shadow can be twisted to the right or to the left.

The little indicator was placed entirely within the molecular shadow, no movement being produced. An adjacent electro-magnet being now excited, the shadow was twisted half off the indicator, which immediately rotated with great speed.

The Trajectory of Molecules.

The amount of deflection of the stream of molecules forming a shadow is in proportion to the magnetic power employed.

The trajectory of the molecules forming the shadow when under magnetic influence is curved, the action of the magnet is to twist the trajectory of the molecules round in a direction at an angle to their free path, and to a greater extent, as they are nearer the magnet. The direction of twist being that of the electric current passing round the eletro-magnet.

Laws of Magnetic Deflection.

An apparatus was constructed so that the deflection of a spot of light was used instead of that of a shadow; a horseshoe magnet being placed underneath the negative pole to deflect the trajectory. The action of the north pole being to give the line of molecules a spiral twist one way, and that of the south pole being to twist it the other way, the two poles side by side cause the line to move in a straight line up or down along a plane at right angles to the plane of the magnet and a line joining its poles.

The ray of molecules does not obey Ampère's law, as it would were it a perfectly flexible conductor, joining the negative and the positive pole. The molecules are projected from the negative, but the position of the positive pole, whether in front, at the side, or even behind the negative pole, has no influence on their subsequent behaviour, either in causing phosphorescence, producing mechanical effects, or in their magnetic deflection. The magnet only gives their line of path a spiral twist, greater or less according to its power, but diminishing as the molecules get further off.

Numerous experiments were tried in this apparatus with different gases, and with the magnet in and out of position, and the following conclusions are arrived at:—

Working with exhausted air it was found that the spot of green phosphorescence on the screen was visible at an exhaustion of 102·6 M when the mean free path of the molecules, measured by the thickness of the dark space round the negative pole was only 12 millims. Hence, it follows, that a sufficient number of molecules to cause green phosphorescence on the screen are projected the whole distance from the pole to the screen or 102 millims, without being stopped by collisions.

Alteration of Molecular Velocity.

If we suppose the magnet to be permanently in position, and thus to exert a uniform downward pull on the molecules, it is seen that their trajectory is much curved at low exhaustions, and gets flatter as the exhaustion increases. A flatter trajectory corresponds to a higher velocity. This may arise from one of two causes; either the initial impulse given by the negative pole is stronger, or the resisting medium is rarer. The latter is probably the true cause. The molecules which produce a green phosphorescence must be looked upon as in a different state to those which are arrested by frequent collisions. The latter impede the velocity of the free molecules and allow longer time for magnetism to act on them; for, although the deflecting force of magnetism might be expected to increase with the velocity of the molecules, Professor Stokes has pointed out that it would have to increase as the square of the velocity, in order that the deflection should be as great at high as at low velocities.

Comparing the free molecules to cannon balls, the magnetic pull to the earth's gravitation, and the electrical excitation of the negative pole to the explosion of the powder in the gun, the trajectory will be flat when no gravitation acts, and gets curved under the influence of gravitation; it is now also much curved when the ball passes through a dense resisting medium, it is less curved when resisting medium gets rarer; and, as already shown, intensifying the induction spark, equivalent to increasing the charge of powder, gives greater initial velocity, and, therefore, flattens the trajectory. The parallelism is still closer if we compare the evolution of light seen when the shot strikes the target, with the phosphorescence caused in the glass screen by molecular impacts.

Focus of Heat of Molecular Impact.

The author finally describes an apparatus in which he shows that great heat is evolved when the concentrated focus of rays from a nearly hemispherical aluminium cup is deflected sideways by a magnet on to the walls of the glass tube. By using a somewhat larger hemisphere and allowing the negative focus to fall on a strip of platinum foil, the heat rose to the melting point of platinum.

An Ultra-gaseous State of Matter.

The paper concludes with some theoretical speculations on the state in which the matter exists in these highly exhausted vessels. The modern idea of the gaseous state is based upon the supposition that a given space contains millions of millions of molecules in rapid motion in all directions, each having millions of encounters in a second. In such a case, the length of the mean free path of the molecules is excessively small as compared with the dimensions of the vessel, and the properties which constitute the ordinary gaseous state of matter, and which depend upon constant collisons, are observed. But by great rarefaction the free path may be made so long that the hits in a second are negligible in comparison to the misses, and the average molecule is allowed to obey its own motions or laws without interference; and if the mean free path is comparable to the dimensions of the vessel, the properties which constitute gaseity are reduced to a minimum, and the matter becomes exalted to an ultra-gaseous state, in which the new and very decided properties now under investigation come into play.

Rays of Molecular Light.

In speaking of a ray of molecular light, the author

66

has been guided more by conciseness of expression than by a wish to advance a novel theory. It is considered, however, that the comparison, under these special circumstances, is strictly correct, and that he is as well entitled to speak of a ray of molecular or emissive light when its presence is only detected by the light evolved when it falls on a suitable screen, as he is to speak of a sunbeam in a darkened room as a ray of vibratory or ordinary light when its presence is only to be seen by int... ... in its path. When the glass bulb was strongly heated by a spirit flame the leaves suddenly discharged and fell together.

Another bulb (fig. 2) was prepared, containing a plate of mica *a*, which could be suddenly placed between the gold leaves *b b*. The plate of mica was longer and wider than the gold leaves, and was connected with a small piece of iron wire, capable of moving up and

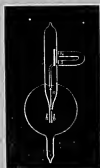

FIG. 2.

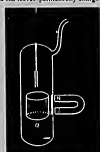
down a tube sealed into the top of the bulb. By means of an outside magnet the mica plate could thus be lowered between the gold leaves or raised out of their way, as desired. The tube was exhausted to about the millionth of an atmosphere, the mica plate being held quite above the leaves. One side of the bulb was then heated, and the leaves permanently charged by means



instead of a mica plate coming between the leaves, a mica cylinder *a*, was made capable of being raised and lowered outside the divergent leaves. I was not able to get entirely concordant results with this, owing to the friction of the mica developing electricity on the inner surface of the glass tube; but in all cases, when the cylinder was raised until it covered the electrified

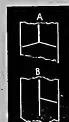


FIG. 4A.

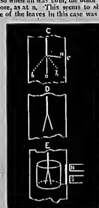
leaves, it had the effect of diminishing the angle which they formed with each other.

The following experiments were also tried. The leaves being separated about 160°, as at fig. 4A, one side of the tube was slightly heated by a spirit flame. The leaf on that side fell to a vertical position, and remained so when all was cold, the other leaf sticking out as before, as at B. This seems to show that the divergence of the leaves in this case was not so much



ON ELECTRICAL INSULATION IN HIGH VACUA.

By WILLIAM CROOKES, F.R.S.

The experiments here described were tried nearly two years ago. They were suggested by some observations I was then making on the passage of an induction

67

with a lamp, the leaf was repelled down, but not so readily as the other had been, and when the tube got cold, it rose to nearly its former position. This was repeated several times with uniform results. When the leaf was repelled down, the vertical leaf also moved away, so as to keep the same angle between them. This shows that the leaves themselves were also charged.

Fig. 4, C, shows the two positions of the leaves, *a a* before applying heat to the side *c* of the tube, and *b b* after heating the glass at *c*.

The tube was now heated on both sides, causing the leaves to come nearer together, as shown at fig. 4, D. While the glass was warm the cylinder was raised so that it surrounded the leaves; this caused them to get a little closer together, and they kept in this position, shown at E, till the whole apparatus was quite cold.

After remaining thus for some time, the cylinder was lowered, when the leaves widened out and took up the position shown at *b b*, fig. 4, C. The leaves did not return to the position *a a*, showing that now their divergence was owing to their own mutual repulsion, and not to an attraction of one or other to the electrified glass.

In December, 1877, I totally immersed one of these exhausted glass bulbs in a vessel of water; the gold leaves having previously been charged, and standing at an angle of 112° from one another, as at fig. 5. The

FIG. 5.

water was connected electrically with "earth," and the whole was set aside in a cabinet on the 1st of January, 1878.

At the present time, after having remained in this condition for thirteen months, the leaves form exactly the same angle with one another which they did when they were first put in the cabinet.

After this experience I think we may consider that at an exhaustion of a millionth of an atmosphere, air is an absolute non-conductor of statical electricity. It is, therefore, legitimate to conclude that the vacuum of interstellar space offers equal obstruction to the discharge of electrified bodies, without necessarily interfering with their mutual repulsion if similarly electrified. It is possible that in these facts an explanation may be found of some obscure celestial phenomena.

EXPERIMENTAL RESEARCHES ON THE REPULSION RESULTING FROM RADIATION[1]

II.

HAVING completed the experimental investigation of the amount of repulsion produced by radiation on disks of various kinds, and coated with different substances, I turned my attention to the amount of repulsion produced when polarised light is allowed to fall on a plate of tourmaline suspended in vacuo in a torsion balance. It was originally thought that a slice of tourmaline, being black to a ray of light polarised in one plane, and white to a ray polarised in the other plane, would be repelled when the incident light was quenched by it, and not affected when the incident light passed through it. Experiments, however, prove that this action does not exist in any

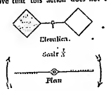


FIG. 4.

appreciable degree, the repulsion resulting from radiation being almost entirely a surface action, whilst the action of a tourmaline on a ray of polarised light is one in which thickness is necessary.

I next examined the effect of shape in influencing the amount and direction of repulsion. These experiments were for the most part tried with the apparatus shown in Fig. 3 (p. 513, part I.). Through the open top access can readily be obtained, and disks, plates, &c., can be quickly tested by being fixed to the extremities of a pair of aluminium arms, with a glass cap in the centre, rotating on the needle-point. Plates, 12 millims. square, cut from thin aluminium foil, were mounted diamond-wise on arms, and supported on the needle-point inside the bulb. The plates were lampblacked on sides facing

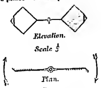

FIG. 5.

opposite ways, and the apparatus was well exhausted. The vanes behaved like an ordinary metal radiometer in respect to light and radiant heat. Fig. 4 shows the elevation and plan of the fly, the dotted side representing the one which was lampblacked. The arrows show the direction of positive rotation when exposed to the light of a standard candle 3·5 inches off. The outer corners of the aluminium plates were now turned up at an angle of 45°, 4 millims. of the two sides being turned up, leaving 8 millims. flat, as shown in Fig. 5. They were lampblacked on the inside, as shown in the figure by dots. A lighted candle 3·5 inches off caused very slow and feeble positive rotation. On shading the light from the black side, the bright side was repelled, causing positive rotation; and on shading the light from the bright side the black was repelled, causing negative rotation.[1] The positive repulsion was, however, rather stronger than the negative repulsion, so that, when both sides were illuminated, the force was only that due to the difference of these repulsions.

A hot glass shade is a convenient means of heating the bulb, by immersing it in a hot-air bath, without the liability of introducing action of rays other than those emitted by hot glass. On inverting a hot glass shade over the bulb in the above experiment, negative rotation was produced which changed to positive on cooling. Both these rotations were stronger than that given by the candle. The experiment was varied (1) by 6 millims. of the sides being turned up instead of 4; (2) by folding the plates across the vertical diagonal and then across their horizontal diagonal; (3) by attaching flat

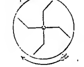

FIG. 6.

plates to the arms at an angle of 45°, blacking them on the insides away from the bulb, and repeating the experiment with plates blacked on the outsides. The results obtained show that when flat plates are taken blacked on alternate sides, the rotation is normal or positive, *i.e.*, the black side is repelled. When the outer corners of each plate is turned up so as to keep the blacked surface on the concave side, the positive rotation is either diminished, stopped, or converted into negative rotation, according to the amount of surface of the plate which has been turned up. The favourable presentation of the surface of the vanes to the inside of the bulb has more influence on the movement than has the colour of the surface. Radiometers constructed with silver flake vanes set at an angle

FIG. 7.

of 45° and blacked on the outside prove the most sensitive for light hitherto constructed.

I now endeavoured to clear up many anomalous results which had attended the application of heat either by hot shades or by hot water to radiometers. There was an antagonistic action between the effect of shape and that of colour of surface, the two actions sometimes acting together and sometimes in opposition.

Five radiometers were made exactly alike in size of bulb, shape of vanes, and degree of exhaustion, only differing in the material of which the vanes were composed. No. 1 was made of mica, 0·003 inch in thickness; No. 2, of mica, 0·0005 inch in thickness; No. 3, of pith,

[1] Continued from p. 514.

[1] I call the rotation *positive* when the black or driving side is repelled, and *negative* when the side which under ordinary circumstances would be the driving side, moves towards the light.

from a hot pole of the bulb will strike the *inner* surface of the sloping vanes, and driving them before it, will cause a rotation which appears *negative* to an observer, although it is really *positive* to the direction of pressure. Fig. 11 sufficiently illustrates this mode of action. The heat is supposed to be applied near the centre, and the molecular pressure, radiating on all sides, presses the vanes chiefly on the inner surfaces. The anomalous results obtained when the radiometers were heated with hot glass shades or hot water are thus accounted for. Polar heating gives *negative*, and equatorial *positive*, rotation, and when both are applied together by immersion in hot water, the direction of motion is governed by the stronger of these two forces.

In my description of Fig. 7 (p. 534) I showed that the glass heated by the ultra-red rays became hot, and acted on the driving surface, generating molecular pressure, and causing the sloping vanes to turn in the positive direction. At the same time the vanes get warm and become themselves sources of molecular pressure. The amount of molecular pressure thus generated depends on the capacity of the material of the vanes to absorb heat. Thin mica will hold very little, thick mica will hold more, and aluminium will hold most. This extra capacity for heat causes more molecular pressure to proceed from the aluminium and thick mica, and generates a proportionate amount of driving power on the surfaces of the vanes, turning them in the positive direction, and supplementing the action of the equatorial ring of hot glass.

The next subject of investigation was the action of radiation on cones, cylinders, and cup-shaped vanes. A pair of

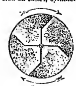

Fig. [illegible]

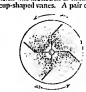

Fig. 11

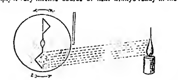

Fig. 12

thin aluminium disks, cut half across the diameter, were bent into cones and mounted on two arms as a radiometer, the cones facing opposite ways. Several experiments were tried and repeated with cones of different material. The movement which appeared most anomalous was the attraction observed when a candle was allowed to shine on the hollow side of a cone or cup-shaped radiometer, the light being screened off the retreating side. Further experiments, however, showed that the effect of bending the plates, or of making cones of them, is to produce a more favourable presentation to the inner surface of the glass bulb. Radiation falls from the candle on the aluminium; some is reflected and lost, but a portion is absorbed, to be converted into thermometric heat or heat of temperature. Aluminium being a good conductor of heat, and the thickness of metal being insignificant, it becomes equally warm throughout, and a layer of molecular disturbance is formed on each surface of the metal. At a low exhaustion the thickness of this layer is not sufficient to reach from the metal cone to the side of the glass bulb; as the exhaustion increases, this layer extends further from the generating surface, until at a sufficiently high exhaustion the space between the side of the glass bulb and the adjacent portion of the metallic cone is bridged over, and pressure is exerted between the two surfaces. Fig. 12 shows how this pressure will act. The direction of pressure is indicated by dotted lines issuing from the metal cone. The more favourable presentation offered by the cone causes the pressure to be greatest between the glass bulb and the outside of the cone; the pressure from the inside of the cone and from the outside, away from the side of the glass, is dissipated without acting, but the pressure between the glass bulb and the side of the cone nearest to it is active; the cones, therefore, are pressed round in the direction of the arrows, and the motion has the appearance of *attraction*.

Cones being inconvenient in shape, I employed portions of cylinders wherewith to shape the vanes, and I ultimately found that cups were more easily affected by radiation than portions of cylinders, whilst they are more easily fashioned. I found that a four-armed cup-shaped aluminium radiometer, the cups being bright and 10 millims. in diameter, and the radius of the curvature being 6 millims., rotates in the light as well as a flat vaned instrument. I sealed one of these instruments on to the mercury pump. During exhaustion accurate observations were taken of the number of revolutions per minute caused by one or more standard candles 3 inches from the centre of the bulb. I also took observations of pressure, and the exhaustion was carried to a very high point. Fig. 13 shows the curve plotted from these observations, taking the rarefaction of the air in millionths of an atmosphere as abscissæ, and the number of revolutions a minute as ordinates. The curve traced through the dots representing observations illustrates the gradual increase of sensitiveness up to a certain point of rarefaction, and the sudden drop after that point is reached.

To still further investigate the action of dark heat on the vanes, I contrived an apparatus to which I could apply a very intense source of heat always ready in the same place, the heat not having to pass through glass, and being completely under control as to intensity and time of action. The instrument with which I performed the great number of these experiments is shown in Fig. 14. The cylinder is sealed at the top so as to permit of the highest possible exhaustion. It is drawn off narrow at the end, and a stem is sealed in to hold a needle-point. To the narrow end a fine tube is attached to connect the apparatus to the mercury-pump. Round the needle is placed a ring of fine platinum wire, *a a*, the ends of which are joined to thicker platinum wires passing through the glass. The fly consists of four square vanes of clear mica, *b b*, inclined at an angle of 45° to the horizontal plane and supported on light aluminium arms. Above the vanes is a flat disk of clear mica, *c c*, having a glass cap in its centre, and easily rotating on a needle-point. The vanes and the mica disk are supported independently of each other on separate needle points, which are held in glass rods, *d, d, d*. A current of electricity from two Grove's cells, turned on or off by a contact key, gives the power of making the wire ring, *a a*, red hot when desired.

The normal or positive movement of the disk is in the opposite direction to that of the vanes; thus, if the positive movement of the vanes is in the direction of the hands of a watch, the positive movement of the disk is in the opposite direction. With the apparatus full of air at the ordinary pressure (bar. = 761 millims.) the direction of rotation, both of the vanes and disk, is *positive* when the platinum wire is ignited. The speed of the vanes is 13·3 revolutions a minute, and that of the disk t a minute

70 72

EXPERIMENTAL RESEARCHES ON THE REPULSION RESULTING FROM RADIATION

IN previous papers[1] I have described my earlier experiments with the radiometer, and I then showed that the movement of this instrument was due to the presence of residual gas. I have since examined the repulsion exerted by a standard flame shining on pith and mica disks, coated with various powders, chemical precipitates, &c., and suspended *in vacuo* in a torsion apparatus, and I propose in this and succeeding papers to give an account of these experiments, and of the concluding researches on the repulsion resulting from radiation.

The apparatus I used to get quantitative measurements of the repulsion produced by radiation on various kinds of disks, and coated with different substances, is similar to one I have already described, but in order that the experiments may be better understood, it is shown in Fig. 1. I append the following description:—

ab is a horizontal glass tube containing the beam,

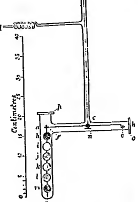

Fig. 1.

which, in this case, is made of straw, so as to secure lightness with absence of flexure under the comparatively heavy weights it sometimes has to bear; *cd* is a fine torsion fibre drawn from flint glass, to which the beam is suspended; it is cemented at *d* to a well-ground stopper, so as to admit of adjustment. When in position, cement, made by fusing together eight parts by weight of resin, and three parts of bees' wax, is run round the stopper. At *c*, the point of junction between the torsion-fibre and the straw beam, is a silvered glass mirror. At the end *e* of the beam, is a small pan to hold the weights counterpoising the disks, which are suspended to the other end. A flat stirrup of aluminium at *f* fits stiffly on the straw beam, and carries a flat glass fibre, *fg*, cemented to it so as to allow of no play, the straw beam, the aluminium hook, and the glass fibre being perfectly rigid. The experimental disks are fixed on the glass fibre by means of a touch of cement at the back. The vertical tube is arranged to hold six disks, the top one, *h*, being always the same standard lamp-blacked pith; the others, *i*, *j*, *k*, *l*, and *m*, being changed each time. A small magnet, *n*, attached to the central mirror, and controlled by a bar-magnet outside, gives the power of bringing the beam to zero, should it happen to get out of adjustment, without having to melt the cement and alter the angle of the torsion fibre by turning the stopper *d*. Plate glass caps at *o* and *p*, cemented to the ground edges of the tubes, give access to the interior; *o* allows the counterpoises to be adjusted in the pan, and *p* allows the aluminium stirrup to be unhooked, and the whole of the disks to be lifted out together. The apparatus is connected to the mercury pump by the arm and spiral *q*. The weights and dimensions of the various parts of the apparatus are as follows:—

Weight of straw beam, mirror, magnetic needle, aluminium stirrup, and flat glass fibre, &c.	7·25 grains.
Average weight of six plain mica disks ...	2·40 "
Average weight of six plain pith disks ...	0·59 "
Length of straw beam, from centre of counterpoising pan to centre of disks	17·0 centimetres.
Length of arm from centre of suspension to centre of pan	7·6 "
Length of arm from centre of suspension to centre of disks...	9·4 "
Glass torsion fibre—Length	23·0 "
" " Thickness	0·0013 inch.
Torsion with a glass weight hanging from it	½ oscillation in 15·75 seconds.

Fig. 2 shows the apparatus fitted up for experimentation. The disks are shown in position at *a*; a brick wall, *bc*, has holes pierced through it in two places, as shown, one hole, *d*, being opposite the centre mirror, and the other, *e*, opposite the disks. The aperture *d* is lined with card, lampblacked inside, and the interstices between it and the bricks are well plugged with cotton wool. A water cell at *d* prevents radiant heat from the lamp getting to the apparatus. Through the hole *e* pass six card tubes, lampblacked internally, 20 millims. diameter, and 23 centims. long. The tubes are firmly cemented to the wall, so that each shall be exactly central with its corresponding disk, and the outer end of each is closed with a cork. The space between the tubes and wall is well stuffed with cotton wool. The apparatus, being once fixed in position, is surrounded on all sides, as well as above and below, with cotton wool. Outside this is a row of glass bottles filled with water, and in front of all is a wooden screen. When protected in this manner, the inside of the apparatus is found to be free from disturbances caused by changes of temperature. When the disks have to be changed, air having been let in through the pump, access is easily obtained to the glass cap *p* (Fig. 1), and the cement being softened by heat, and the cap removed, the disks are lifted out together by seizing the aluminium stirrup with forceps. A fresh set of disks being introduced, the apparatus is again packed up and re-exhausted.

A lamp at *f* throws a narrow beam of light on the mirror of the apparatus, through the aperture *d*. The ray is reflected to the scale *g*, where its deflection from zero shows the angular movement of the torsion beam when one of the disks is repelled by radiation. The scale is 1½ metre from the reflecting mirror.

A standard candle (the kind employed in gas photometry, and defined by Act of Parliament as a "sperm candle of six to the pound, burning at the rate of 120 grs. per hour") is supported on a heavy stand, *h*, and can be raised or lowered by means of the sliding piece, *i*. Another sliding piece, *j*, carries a pointed wire projecting from it. The upright rod of the stand is graduated and numbered, so that when the sliding piece *j* is at mark 1,

74

THE ROYAL SOCIETY SOIRÉE, 1879.

The conversazione which was given at Burlington House by the President and Council of the Royal Society on the evening of Wednesday, the 30th of April, was an exceedingly brilliant and successful one, and was in no way inferior to any that has gone before it, whether for the number of distinguished guests who availed themselves of the invitation, or for the importance and scientific interest of the objects collected for their pleasure and instruction.

As is usual on these occasions, Mr. William Crookes, F.R.S., contributed very largely to the success of the evening by his superb display of experimental illustrations of a branch of physical research which he has made his own quite as much as his celebrated investigations connected with Repulsion resulting from Radiation, which gave it birth. This new research, the investigation of certain phenomena connected with molecular physics in high vacua, Mr. Crookes first brought before the Royal Society in the month of December last, and it was treated in our article on the "Trajectory of Molecules" immediately after.* In that article we pointed out that Mr. Crookes's experiments tended to show that there exists in nature a fourth and higher condition of matter as much more ethereal than the gaseous condition as the gaseous state is higher than the liquid. Such experiments of Mr. Crookes as have produced the Radiometer, the Otheoscope, and the exceedingly beautiful series of experimental researches upon which he is still engaged, would have been impossible even to have been commenced before the days of the Sprengel pump, but Mr. C. H. Gimingham, by his great and important improvements in that instrument, has placed in the hands of the physicist an instrument by which vacua can be produced, compared with which the highest exhaustions effected by the old-fashioned air pump must be regarded almost as high pressures. The internal pressures of the gaseous residues within Mr. Crookes's apparatus are measured in millionths of an atmosphere, and in many of his more recent researches he has had to deal with vacua whose pressure is measured in small fractions of but one millionth of an atmosphere.

In the article to which we have already referred, we described Mr. Crookes's experiments which led to the discovery that the dark space around the negative pole within a vacuum tube, and separating it from the luminous nebulous glow, is a field of molecular activity which appears to bear a very close relationship to, if it is not identical with, the field of molecular disturbance in front of the vanes of a radiometer and by which its mechanical motion is produced. Fig. 1 represents a small apparatus in

Fig. 1

which this dark space is very beautifully shown. A A is a cylindrical vacuum tube having an aluminium wire sealed into each end at C C, and carrying across its middle diameter a circular disc B of aluminium, which is of slightly smaller diameter than the tube, and is connected by the wire shown in the sketch to the negative pole of an induction coil, the two wires C C both being connected to the positive pole. When this exhausted tube is placed in electrical communication with the induction coil, the tube is filled right and left of the disc B with a beautiful nebulous violet glow, with the exception of a space on each side of the disc shown at D D; this is the dark space around the negative pole, and its width from the disc increases as the exhaustion is continued, and if this be carried on sufficiently it will spread to the two ends of the tube, driving the luminous glow before it. When the negative pole is free to move like the vane of a radiometer and one of its faces is insulated by a film of mica, no motion takes place until the exhaustion is such that the dark space reaches the surrounding glass envelope or tube, and the moment that this occurs rotation commences. The electrical radiometer which we figured

* See Engineering, vol. xxvi., page 183.

and described in the article above referred to,* embodies this principle and consists of a radiometer carrying flat aluminium vanes, each of which is covered on one face with a thin disc of mica; this fly is in metallic communication through its centre with an induction coil of which it forms the negative electrode. The positive electrode can be inserted in any other part of the bulb, its position in no way affecting the result. When the induction coil is placed in circuit with this apparatus the luminous glow gradually separates from the metallic surface of the vanes under exhaustion, leaving a dark space, which widens as the exhaustion is continued until the inner surface of the envelope or bulb is reached, when rotation of the fly immediately commences. This little instrument, which was shown by Mr. Crookes at the soirée, besides illustrating the very beautiful phenomena for which it was designed, exhibited some interesting optical effects; thus, whenever the number of vibrations of the contact-maker bore an exact proportion to the speed of rotation of the fly, it appeared to be standing perfectly still although really rotating at a high velocity, the number of vanes seen depending upon what the proportion was between the two speeds; these effects, which are familiar to those who have played with the colour top, especially when illuminated by electrical discharges, were especially strikingly illustrated in the instrument to which we refer, for the reason that the rotating object was at the same time the source of light by which it was itself illuminated. Similar effects were produced with a radiometer, the vanes of which were aluminium cups.

We have on a former occasion† referred to the very beautiful phosphorescent effects produced by molecular impact in tubes, in which the exhaustion is carried to high degree. With the ordinary soft German glass of which Mr. Crookes's tubes are generally constructed, this phosphorescence displays itself as a beautiful greenish yellow light spread over all those portions of the glass upon which the molecular stream impinges, and appears to be due to the sudden arrest of the gaseous molecules which are projected at a high velocity against the inner surface of the glass by a species of bombardment, their motion being suddenly arrested, and their energy being thereby converted into luminous effects.

We have also pointed out that if any body, whether optically transparent or not, be interposed between the negative pole and the surface which is rendered phosphorescent by the molecular bombardment, a sharply-defined shadow of the object is cast upon the glass, that is to say, the interposed body acts as a shield or screen, arresting the streams of molecules projected in straight lines from the negative pole, and allowing only those portions of the glass to be subjected to molecular impact which are not screened from the negative pole by the object placed in the molecular path. This beautiful effect was illustrated by Mr. Crookes with the very simple

Fig. 2.

little apparatus shown in Fig. 2, in which A A is a pear-shaped vacuum tube or bulb having a flat aluminium disc B fixed at one end; in connexion with the negative electrode C of an induction coil is a Maltese cross cut out of thin aluminium foil fixed to a hinged support, so that it can be set up or laid down flat against the lower side of the tube, by slightly shaking the apparatus. For convenience this is made the positive electrode, but there is no other necessity for the cross C being electrically connected with the coil, as its only object is to present a screen or obstruction to the molecular streams projected from the disc B upon the end of the bulb. When this cross is lying flat at the bottom of the tube it offers no obstruction to the molecules in their path, and the larger end of the tube glows with the beautiful green "phosphorescent" light of molecular impact, but the moment that the cross is set up so as to stand in the path of the stream, a perfectly sharply-defined shadow is cast at D, producing a non-luminous transparent cross upon a green semi-opaque and luminous ground, indicating by its sharpness that the molecular streams are projected in perfectly straight lines, and in no way curve round an object or overlap one another. If, however, a magnet be brought near to the apparatus, these streams are deflected up or down, right or left, according to the position of the poles with respect to the tube, and in that case their paths become curved. This is shown by the shifting about of the shadow at the end of the tube, its position altering with every movement of the magnet, but its sharp definition remains the same. This magnetic deflection of the trajectory of molecules may be compared to the effect of gravitation upon the path of a cannon ball projected from a gun in a horizontal direction; if the action of gravitation were eliminated, the trajectory of the shot would be a horizontal straight line, but the action of gravitation combined with the constantly diminishing inertia of the ball, gives curvature to its trajectory.

As the molecular streams are projected from the negative pole in straight lines which start in a direction normal to the surface of that pole, it is perfectly easy by giving to that pole a plane or a curved surface to concentrate the molecular streams to a focus, to cause them to diverge or to move in parallel straight lines, and Mr. Crookes has made a large number of experiments with cup-shaped poles by which effects of concentration are produced; one of the most striking of this most superb series of experiments is one which, although we have described it before, we cannot omit on the present occasion, as it formed one of the principal demonstrations shown by Mr. Crookes the other evening. This experiment is the production of intense heat by the concentration of streams of molecules upon a focal point, which thus receives the combined impacts of the great majority of the molecules projected from the negative pole. The apparatus by which Mr. Crookes demonstrated this beautiful phenomenon is shown in Fig. 3. A negative pole a, which is in the

Fig. 3.

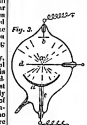

Fig. 4.

Fig. 5.

form of a large cup of spherical curvature, is fixed by the stem c at the lower portion of a glass bulb similar to that of a radiometer, the positive pole b being fixed at the top of the bulb. At d is placed a narrow strip of platinum foil, at such a distance from the cup-shaped electrode a as to pass through its centre of curvature x. From what has already been said it will be seen that when the two electrodes are connected to the poles of an induction coil, a concentrated fire of molecular projectiles is received upon the platinum strip d at the point x, and the effect is to cause this point at once to glow with incandescence, and so great is the heat produced that unless the action be promptly stopped the platinum would be fused and the instrument destroyed.

This little apparatus shows in a very beautiful manner the deflection of the molecular streams under the influence of magnetism, for if a magnet be manipulated near the bulb the incandescent spot may be made to travel to and fro along the platinum strip or directed to any one point, or by deflecting it to the right or left of the strip it may be thrown off it altogether, no incandescence being produced.

For the exhibition of the "phosphorescent" effects of molecular impact, the tube shown in Fig. 4 is perhaps the most striking; it consists of a cylindrical tube A A, having a semi-cylindrical negative pole C at its lower end. Above this is fixed a phosphorescent screen or plate B B coated with M. Becquerel's luminous sulphide of calcium. When this tube is placed in circuit with the induction coil the field of molecular disturbance is splendidly marked out by the phosphorescent figure on the screen, the planes of molecular streams first being brought to a focus, which is shown by the small area and greater brilliancy of their point of intersection, and then, diverging again, producing a surface of illumination diminishing in intensity as the distance from the focus is increased. The light emitted from this tube was strong enough to enable objects to be seen in an otherwise dark room, and it was perfectly possible to read small print when the paper was held near the illuminated tube. For optical beauty, however, the tube shown in Fig. 5 was perhaps the most remarkable of the whole series. In construction it differed from the last piece of apparatus only in being without the flat phosphorescent screen, the beautiful effects being produced by the green phosphorescence of the tube itself. A A is a cylindrical vacuum tube having a semi-cylindrical electrode at C, which is connected with the negative pole of an induction coil. When the circuit of the coil is completed, the beautiful green light of molecular impact that is produced, and the planes of disturbance intersecting in a sharply defined focal line crossing and impinging on the opposite cylindrical surfaces of the glass envelope so as to form ellipses of brilliant green phosphorescence, can hardly be imagined without being seen, and the action of the cylindrical electrode being to condense the molecular streams in one plane but not in others, produces the effect of two flat surfaces of elliptic boundary crossing one another, the space between and above them being filled with a beautiful but less intense illumination.

Fig. 6 represents an apparatus which illustrates

Fig. 6.

in a very beautiful manner, the four principal phenomena connected with molecular physics in high vacua; first, the green phosphorescent light of molecular impact, second, the projection of molecular shadows, third, the magnetic deflection of the trajectory of molecules, and fourth, the mechanical action of the gaseous molecules projected from the negative pole. A A is a vacuum tube carrying at C a concave circular negative electrode whose centre of curvature falls about the middle of the tube, at this spot a light wheel B is pivotted upon a horizontal axis. This wheel, which is shown enlarged in Fig. 7, consists of a disc of thin mica

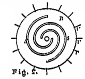

Fig. 7.

carrying around its periphery a number of equidistant radial vanes of aluminium, whose planes are perpendicular to the plane of the disc. The wheel, therefore, bears some resemblance to a water-wheel. When this tube is placed in connexion with the induction coil, a concentrated stream of molecules is projected on to the wheel, which is pivotted at or near the focus of the electrode C, and falling neither above nor below its axis, no rotation takes place; but when a small magnet M, which can be turned on a vertical axis, is put into such a position that the cone of molecular rays is bent upwards, the focus of impact is received by the upper vanes, and the wheel rotates with great rapidity in the direction indicated by the arrow. On however reversing the position of the magnet, the molecular streams are repelled, and falling on the lower vanes of the wheel, cause it to revolve in the opposite direction. To express the effect in a very few words, one position of the magnet converts the movement into an over-shot wheel, another position into an under-shot wheel, while the intermediate position, by allowing the stream to strike the wheel equally above and below its centre, has no motive effect upon it, and consequently it remains at rest. In order to make the rotation of

THE ELECTRIC DISCHARGE WITH THE CHLORIDE OF SILVER BATTERY

MESSRS. De La Rue and Müller, in the second part of the researches which they have carried on during three and a half years, have contributed facts of the highest value towards the solution of the problem presented by the beautiful phenomenon of stratification produced by electric discharges in vacuum tubes. The following are some of the more important results of these experiments as described by the authors.[1]

These phenomena, first noticed by M. Abria in 1843, were independently re-observed by Mr. (now Sir William) Grove in 1852, and have since engaged the attention of many physicists. The late Mr. Gassiott, working at first with an induction coil, but more recently on the same lines as the voltaic batteries of high potential,[2] published results of great interest; while, on the other hand, Mr. W. Spottiswoode is still pursuing with great acumen and originality a similar investigation, both with the induction coil and the Holtz machine, with which he has recently used condensers of great capacity.

Throughout our labours we have felt so strongly the necessity of obtaining numerical results as data for the foundation of a theory, that we have not hesitated to risk much in this cause. By the fusion of terminals, or the sudden discharge of the condenser, we have lost a vast number of very beautiful tubes; but gradually by the adoption of various devices, and by the employment of instruments specially constructed and insulated to suit the high potentials we deal with, we have succeeded in overcoming the various impediments, so that we can now readily obtain values for the physical quantities that enter into consideration in our experiments.

There is a serious trouble connected with the study of the discharge in rarefied gases, for, after a very short time, the tubes completely and permanently change, so as no longer to present the splendid stratifications witnessed on a first trial. We believe these changes occur much more rapidly with the battery in consequence of the greater amount of current, than with the induction coil; but the fact appears to have been well known to Dr. Geissler, of Bonn, who, on the occasion of a visit to our laboratory, brought with him some tubes through which no current had previously passed (virgin tubes, as he called them), which presented most beautiful phenomena lost for ever after too brief a period.

Tube 123 (cyanogen), for example, when first connected with the battery, presented strata which completely filled the tube without leaving a dark space near the negative, some threading themselves on it, as shown on the left of Fig. 1; but after a few seconds the strata widened out as on the right hand figure, then other changes occurred, and the first phases have never been reproduced.

TUBE 123.

Fig. 1.

Another case is presented by the nitrogen tube Fig. 2, the right-hand figure showing the first phase, and the left-hand figure a second phase, which in its turn has for ever disappeared, and has been replaced by the ordinary disk-form of strata.

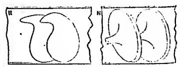

Fig. 2.

After spending much time in experiments with tubes prepared for us by Dr. Geissler, Messrs. Alvergniat Frères, of Paris, and Mr. Hicks, of Hatton Garden, with the vexation of finding that we could not often enough repeat our experiments, we ultimately came to the conclusion to have others made, but not exhausted, and to perform ourselves the charging and exhaustion. The tubes we usually employ have a glass stop-cock fitted to them at each end; they are 32 inches long, and from 1·75 to 2 inches in diameter; the terminals are of aluminium, and about 29 inches apart, one being a ring, the other a wire bent at a right angle, so as to point in the direction of the axis of the tube (see No. 144, Fig. 3), for we have found that the phenomena vary according as the ring or wire is made positive.

Fig. 3.

These we exhaust and fill with any gas we may wish to experiment with, and gradually exhaust again, noting the phenomena presented at different pressures, with different potentials, and with different amounts of current. We re-fill and exhaust the tube again and again, and mostly obtain, under the same conditions, as nearly as possible the same phenomena, of which we are careful to make sketches and, if possible, to obtain photographic records.

In some cases we make use of tubes provided with a calibrated chamber between two stop-cocks, as *a–b*, No. 145, Fig. 4, the chamber in this particular case having $\frac{1}{200}$th of the capacity of the tube, this tube has also an absorption chamber communicating through a cock and intended to contain spongy palladium. After a tube has been exhausted so as to produce a particular phase, and in the course of the experiment the exhaustion has been carried beyond that degree which permits of the reproduction of that phase, one or more charges of gas may be successively admitted into the tube by filling the calibrated chamber with gas at any particular pressure, and then opening the stop-cock communicating with the tube; the lost phase is thus reproduced.

The apparatus which we have found it advantageous to adopt for the exhaustion of our tubes is shown in Fig. 5; it comprises three means of exhaustion which are successively employed as the vacuum becomes more perfect. The first is an Alvergniat high-pressure water *trompe* in connection with the high-pressure water-main of the

[1] See *Phil. Trans.*, vol. clxix., pp. 55-121.

[2] Mr. Gassiot made several batteries of different kinds in the course of his experiments; on the occasion of a visit to his laboratory, January 26, 1875, the current of his Leclanché battery was measured by us with a voltameter. The current of 1000 new cells was found to be 0·07461 W; that of the whole 3000 cells, 2000 of which had been a long time in use, 0·04718 W. Taking the Leclanché as 1·48 volt the internal resistance of the new battery must have been 19·83 ohms per cell; that of the whole 3000, 31·87 ohms per cell. The striking distance of the whole 3000 between a conical point and a disk 0·125 inch diameter was only 0·125 inch; whence the inference is that the insulation was, at that time, imperfect.

74 78

 79

West Middlesex Water Company, the head of water being 106 feet; it produces a vacuum to within half-an-inch (0·47 in. = 12 millims.) of the height of the barometer. The pipe leading to it is so marked in the drawing; it is attached, through a cock, to a four-way-junction-piece F, provided with three more cocks, communicating:—one to one end of the tube T, one to the last drying bottle of the gas generator G G′, and one to a mercurial gauge. The

FIG. 4.

other end of the vacuum tube T communicates by means of a Y-piece to both, an Alvergniat mercurial pump, on the right of the figure, and a Sprengel pump, on the left. After the *trompe* has done its work, the Alvergniat is used for rapid exhaustion, and then shut off by means of the glass cock C, leaving the exhaustion to be completed by the Sprengel; we have thus obtained, by the *pumps alone*, in tubes 32 inches long and 2 inches in diameter, vacua of only 0·002 millimetre pressure, equal to 2·6 millionths of an atmosphere—a vacuum so perfect that the current of 8040 cells would not pass. The apparatus is in connection with a McLeod gauge, by means of which pressures to 0·00005 mm. can be determined. Besides this gauge, the Sprengel and Alvergniat pumps have their own gauges, which read to a millimetre. M is a rotating mirror consisting of a four-sided prism mounted on a horizontal axis and provided with a multiplying wheel; on each face of the prism is fastened a piece of looking-glass. The reflection of the tube in the mirror enables one to examine

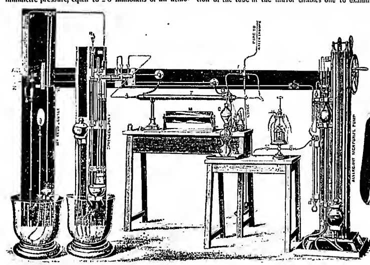

FIG. 5.

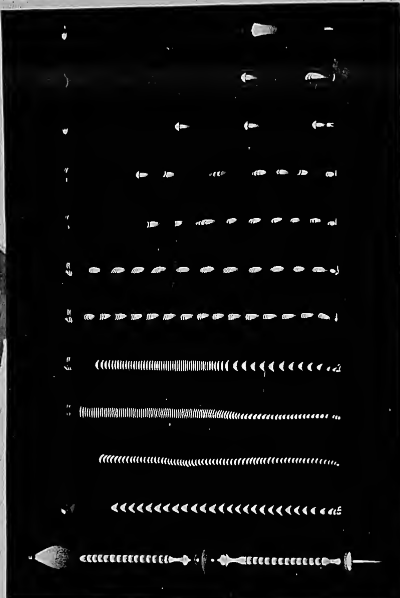
whether an apparently nebulous discharge is simply nebulous or consists really of strata, also whether and in what direction there is a flow of strata which may appear quite steady to the eye. The observations are facilitated by covering the tube with a half cylinder of cardboard having a slit in the direction of its axis about 1/10 inch wide. R is a radiometer attached to the Sprengel; *d, d*, a drying tube containing sticks of potash used when gas is introduced from a reservoir through the Alvergniat.

The resistance of vacuum tubes does not depend solely or mainly on the distance between the terminal, but it does greatly on their diameter.

In order to test how much of this depends on the length of any constriction, we had made two tubes, 154 and 155, Fig. 6, of nearly the same length (16 inches), and internal diameter 1/16ths of an inch, the residual gas in each case being carbonic acid, CO_2. From results obtained with these tubes where the constricture varied in length in the ratio of 125 to 1, it became evident that the main effect is due to the simple constricture of the tube.

The diagram Fig. 7, shows the arrangement by which,

7 80 De La Rue & Müller. NATURE. June 19th 1879



Le Journal July 1879

81

first of these mounds, and then divided into two branches' one of which commenced to flow towards Adernò, and the other towards Biancavilla, but the supply died out at the source, and the new streams solidified at a height of 2,000 metres, having flowed for a mile and a quarter as a stream 400 metres in breadth. This stream did but little damage; it did not penetrate into the cultivated region, and but in short distance into the woody region. It came into contact, however, with a bed of snow, part of which it converted into clouds of steam, while another portion was liquefied and rushed down the sides of the mountain in a foaming torrent, carrying with it a good deal of *débris*.

The outflow of lava ceased on the south side of the mountain, because the lava found a vent at a lower level on the north side. As the one decreased in activity the other increased. On May 28th Silvestri visited the scene of the northern eruption. A great column of smoke appeared about 20° east of north, while a shower of sand descended, producing the "sad leaden light" (*la luce triste plumbea*) observable during an eclipse. More than two pounds of this sand were collected in ten minutes in an inverted umbrella, and the north flanks of the mountain were soon covered with it. Silvestri ascended from Randazzo towards the new craters, and when at a height of about 2,000 metres and near Monte Nero he heard loud subterranean detonations, and perceived severe oscillations of the soil. Soon afterwards he came upon the great rift, together with several smaller ones, converging towards the principal crater. In the immediate neighbourhood of Monte Nerò and Timpa Rossa three new craters were seen, from one of which dense clouds of white smoke issued, while the others emitted lava and showers of ashes and incandescent stones. Frequent flashes of lightning issued from the smoke. The stream of lava near its source emitted a very bright light which, when viewed by a direct vision spectroscope, gave the lines of hydrogen, calcium, sodium, and potassium. The lava flowed downwards at a rapid rate: the wood of Collebasso was destroyed, and by the evening of May 29 it had flowed 6¼ miles, destroying the bridge of Passo Pisciaro and crossing the postal road between Randazzo and Linguaglossa. On Sunday the 31st the stream was rapidly approaching Mojo; the inhabitants became frightened, and brought out the figure of their patron Saint Antony, which was carried in procession to the edge of the stream, while the people fell on their knees and besought the Deity to save them from the impending danger. After the evening of June 1 the force of the eruption began somewhat to abate, and by the 6th inst. it was practically at an end. The lava stream ran nearly 7 miles from its source, and ultimately stopped 500 yards from the river Alcantara, and about half a mile from the village of Mojo. At its termination it is 23 feet in breadth and nearly 32 feet in height. The lava stream entered the bed of the Pisciaro torrent with a velocity of from 4 to 5 metres a minute, which was reduced to 2 metres a minute in the lower valley of less inclination. In 76 hours the lava flowed more than six miles from its source.

Indications of a disturbed volcanic condition were manifest last October, when powerful shocks of earthquake were felt in the territory of Mineo, Palagonia, Vizzini, Scordia, Militello, and Caltagirone. Mineo was the centre of disturbance, and here the shocks continued at intervals during the month of October. Loud subterranean noises were also heard at intervals. Two months later an eruption of mud and gas took place near Paternò, on the southern flanks of Etna. The mud was hot, salt, and petroleum-bearing (*fango salato termale petroleifero*), and its ejectment continued for several months. Towards the end of December last the whole eastern sea-board was visited by a strong shock of earthquake; and soon afterwards a great increase of smoke from the central crater of Etna showed that the dynamic activity of the mountain was unusually near the surface.

Even now we cannot regard the eruption as at an end. Ten days after the cessation of the flow of lava telegrams from Rome (dated June 17) announced that the neighbourhood of Santa Venere and Guardia had been visited by repeated shocks of earthquake. A telegram on the following day announced that "an earthquake of great violence" had occurred near Aci Reale, destroying five villages. There is evidently a great deal of volcanic energy still pent up not far from the surface, and we must fear that before long a further outburst will relieve the imprisoned Titanic forces.

G. F. RODWELL

THE ELECTRIC DISCHARGE WITH THE CHLORIDE OF SILVER BATTERY[1]

II.

THE HISTORY OF A TUBE

No. 129, *Hydrogen*

WE now give an account of the very great variety of phenomena presented by the same tube charged with hydrogen, No. 129 (see Plate), under different conditions of exhaustion when used in connection with batteries of various potentials, and traversed by currents of different strengths.

This tube is 32 inches long and 1·6 inch in diameter, the terminals are a straight wire and a ring, about 1 inch in diameter, both of aluminium; it is furnished with a glass stop-cock at each end, as represented in Fig. 3. The glass stop-cocks are connected with the mercurial pumps (Alvergniat and Sprengel) and with the gas generator respectively, as shown in Fig. 5.

Tube 129, 5*th Charge of Hydrogen.*—A glow at both terminals was first seen when the pressure was 17·2 mm., 22,632 M,[2] with 8,040 cells, and great heat developed in the dark discharge near the middle of the tube. The spectroscope showed faintly the C and F lines.

Pressure 16·5 mm., 21,710 M, 8,040 cells. One luminosity like that on the right hand of Fig. 10, shot out from the positive and approached to within 6 inches of the negative, then receded back and disappeared.

FIG. 10.

Pressure 15·8 mm., 20,789 M, 8,040 cells. 3 luminosities, very steady, which moved slowly and steadily towards the negative. The tube hottest in dark part where there was probably a non-luminous entity.

Pressure 14 mm., 18,421 M, with 6,840 cells, the current was unsteady, but it was perfectly steady with 8,040, and 6 arrow-headed luminosities like that on the left of Fig. 11, were produced and soon disappeared.

FIG. 11.

Pressure 10·3 mm., 13,552 M, with 8,040 cells. 8 luminosities something like 1, Fig. 12.

Pressure 9·4 mm., 12,368 M, with 8,040 cells. 12 luminosities like those, Fig. 7 in the Plate. The C and F lines seen in the glow around the negative.

Pressure 7·7 mm., 10,132 M, with 8,040 cells. 10 luminosities like Fig. 6 in the Plate; these ran together and disappeared and reappeared in a few seconds.

[1] Continued from p. 178.

[2] M = millionths of an atmosphere.

82

Boston Journal of Chemistry July 1879

The explanation of the movement of the radiometer is this: the light, or the total bundle of rays included in the term "light," falling upon the blackened side of the vanes, becomes absorbed, and thereby raises the temperature of the black side; this causes extra excitement of the air molecules which come in contact with it, and pressure is produced, causing the fly of the radiometer to turn round.

H. O.

Electric Discharges in Vacuum Tubes.—Mr. J. F. Moulton demonstrated the results of the experiments of Mr. Spottiswoode and himself on the sensitiveness of electric discharges in vacuum tubes. These experiments were undertaken to find the cause of the numerous layers or strata in the discharge, a Holtz machine being employed. It was observed that when feeble currents were drawn from the machine, the discharge could be depressed by laying the finger on the tube, and this depression always occurs with intermittent currents; therefore the feeble currents from a continuous current Holtz discharge themselves like intermittent currents by reason of their feebleness. This sensitiveness of the discharge to the approach of the finger was found to be due to the conductivity and electric capacity of the hand. Electricity, opposite in kind to the discharge, is induced on the finger, and streaming upon the tube neutralizes part of the discharge therein. This effect was also shown by means of tin foil rings round the tube. An intermittent current is of course capable of this static induction on neighboring conductors. The luminous discharge in a vacuum tube consists of a bright sharp glow at the negative terminal, followed by a dark space, then a hazy bluish light at the positive pole. The striæ or layers in these sensitive tubes merely repeat this appearance. They can be artificially produced by placing the fingers, or rings of metal, at intervals along a tube conveying an amorphous discharge; for in this case the induced electricity discharging itself from the fingers breaks up the amorphous discharge into dark and bright layers. In these stratified discharges the electricity appears to travel *per saltum*, or by stepping stones, as one may say, and the glow seems to be a molecular structure, a view which is supported by Mr. Crookes' experiments. A negative discharge from the finger produces a dark space in the tube discharge, and a positive one a bright line; therefore, one can tell the kind of discharge passing in a tube by laying a finger on it. If the same pole be brought to both ends of a tube, a discharge will take place from each end, and there will be a dark space in the middle, the electricity here seeming to turn back again the way it came. The discharge from the pole through a vacuum tube would therefore appear to be not akin to a conduction but to a disruptive discharge. It is a leap in the dark, and the phenomena observed are due to the gaseous nature of the medium. These experiments point to the possibility of completing a circuit by positive electricity alone.

Professor Guthrie suggested that by combining vacuum tubes with the induction balance of Prof. Hughes, it might be possible to get an optical balance for measuring inductive capacity.

Oxygen in the Sun.—Dr. Henry Draper, of New York, who is now on a visit to England, then addressed the meeting on his alleged discovery of oxygen in the sun by bright lines in the solar spectrum. He said that hitherto he had not been able to find these lines projecting from the limb of the sun like hydrogen, and his impression is that oxygen resides lower than the reversing layer. He had lately been extending the dispersion of the spectrum of terrestrial oxygen, and from a light of maximum intensity of one candle power had now got a dispersion of 80 inches from A to O. He exhibited two of the original negatives of the solar spectrum, showing the bright lines.

Sc. Am. July 26

83

primary to the secondary wire. It was ultimately entirely remade in February, 1878, and the secondary wire coiled on a separate ebonite cylinder to insure efficient insulation, which was accomplished.

In every case where the strata are to the eye or rotating mirror perfectly steady, slight deflections of the needle are seen; these generally indicate a resultant *direct* current (break-contact), and in the fewer number of cases an *inverse* current indicating, in the first case, a *sudden* decrease and *slow* increase of current through the tube. These deflections, though very manifest, do not amount to more than about three or four divisions of the galvanometer scale, a deflection which indicates a current of only 0·0000000023 W. At the advent or retreat of a stratum at the positive pole there is frequently produced a deviation of 300 divisions, indicating a current of 0·0000001812 W; before a stratum leaves the positive terminal or dies out on it, there is usually a tremulous motion of that stratum visible to the eye and indicated by rapid pulsations of the galvanometer.

On the suggestion of Prof. Clerk Maxwell we have recently introduced the telephone into the primary current, as shown in Fig. 20, and also in the secondary current of coil 819.

In all cases where the condenser C was discharging itself gradually through the tube, a low rustling sound was distinctly audible to sensitive ears so long as the stratification remained *apparently* perfectly steady. When the phase of confused stratification which immediately precedes extinction was reached, the sound in the telephone became very loud and rose in pitch, with some tubes becoming quite shrill. These results, therefore, confirm the conclusion already arrived at from other experiments, namely, that the discharge in vacuum tubes is intermittent; but we do not pretend that they make it manifest that stratification is *dependent* upon intermittence.

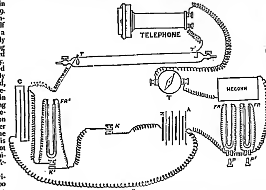


Fig. 20

In the course of our experiments, using sometimes 11,000 cells, we have arrived at the following facts:—

1. *The discharge in a vacuum tube does not differ essentially from that in air and other gases at ordinary atmospheric pressures; it cannot be considered as a current in the ordinary acceptation of the term, but must be of the nature of a disruptive discharge, the molecules of the gas acting as carriers of electrification. The gases in all probability receive impulses in two directions at right angles to each other, that from the negative being the more continuous of the two. Metal is frequently carried from the terminals and is deposited on the inside of the tube, so as to leave a permanent record of the spaces between the strata.*

2. *As the exhaustion proceeds, the potential necessary to cause a current to pass diminishes up to a certain point, whence it again increases, and the strata thicken and diminish in number, until a point is reached at which, notwithstanding the high electromotive force available, no discharge through the residual gas can be detected.* Thus, when one pole of a battery of 8,040 cells was led to one of the terminals of tube 143, Fig. 21, which has a radiometer attached to it, the other terminal of the tube, distant only 0·1 inch, being connected through a sensitive Thomson galvanometer to the other pole of the battery (earth), the current observed was not greater than that which was found to be due to conduction over and through the glass. Although no current passed, the leading wires acting inductively stopped the motion of the radiometer, as has been observed by Sir William Grove.

3. *All strata have their origin at the positive pole.* Thus, in a given tube, with a certain gas, there is produced at a certain pressure, in the first instance, only one luminosity which forms on the positive terminal, then, as the exhaustion is gradually carried further, it detaches itself, moving towards the negative, and being followed by other luminosities, which gradually increase in number up to a certain point.

4. *With the same potential the phenomena vary irregularly with the amount of current.* Sometimes, as the current is increased, the number of strata in certain tubes increases, and as it is diminished their number decreases; but with other tubes the number of strata frequently increases with a diminution of current. If the source of the current is a charged condenser, the flow being from one of its plates through resistances and the tube to the other; then, as the potential of the condenser falls and the current diminishes, the number of strata alters; if the strata diminish in number with the fall of potential, then the stratum nearest the positive wire disappears on it, the next then follows and disappears, and so on with others; if, on the other hand, the charge of the condenser is very gradually increased, the strata pour in, one after the other, in the most steady and beautiful manner from the positive.

Fig. 21.

5. *A change of current frequently produces an entire change in the colour of the strata*: for example, in a hydrogen tube from a cobalt blue to a pink. It also changes the spectrum of the strata; moreover, the spectra of the illuminated terminals and the strata differ.

84

MOLECULAR PHYSICS IN HIGH VACUA[1]

II.

I HAVE hitherto spoken of and illustrated these phenomena in connection with *green* phosphorescence. It does not follow, however, that the phosphorescence is always of that colour. This coloration is a property of the particular kind of glass in use in my laboratory. I have here (Fig. 7) three bulbs composed of different glass: one is uranium glass (*a*), which phos-

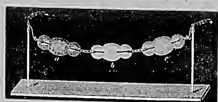

FIG. 7.

phoresces of a dark green colour; another is English glass (*b*), which phosphoresces of a blue colour; and the third (*c*) is soft German glass—of which most of the apparatus before you is made—which phosphoresces of a bright apple-green colour. It is therefore plain that this particular green phosphorescence is solely due to the glass which I am using. Were I to use English glass I should have to speak of blue phosphorescence, but I know of no glass which is equal to the German in brilliancy.

My earlier experiments were almost entirely carried on by the aid of the phosphorescence which glass takes up when it is under the influence of the electric discharge *in vacuo*; but many other substances possess this phosphorescent power, and some have it in a much higher degree than glass. For instance, here is some of the luminous sulphide of calcium prepared according to M. Ed. Becquerel's description. When it is exposed to light—even candlelight—it phosphoresces for hours with a rich blue colour. I have prepared a diagram with large letters written in this luminous sulphide; before it is exposed to the light the letters are invisible, but Mr. Gimingham has just exposed it in another room to burning magnesium, and now it is brought into the darkened theatre you will see the word "φῶς,"—*light*, a very suitable word for so beautiful a phosphorescence—shining brightly in luminous characters. The first letter, φ, shines with an orange light; it is a sulphide of calcium prepared from oyster-shells. The other letters, shining with a blue light, are sulphide of calcium prepared from precipitated carbonate of lime. Once the phosphorescence is excited the letters shine for several hours. I will put the diagram at the back, and we shall see how it lasts during the remainder of the lecture. This substance, then, is phosphorescent to light, but it is also much more strongly phosphorescent to the molecular discharge in a good vacuum, as you will see when I pass the discharge through this tube (Fig. 8). The white plate (*a*, *b*) in the centre of the tube is a sheet of mica painted over with the luminous sulphide of which the letter φ was

FIG. 8.

composed in the diagram you have just seen. On connecting the poles with the coil, the mica screen glows with a strong yellowish green light, bright enough to illuminate all the apparatus near it. But there is another phenomenon to which I now desire to draw attention: on the luminous screen is a kind of distorted star-shaped figure. A little in front of the negative pole I have fixed a star (*c*) cut out in aluminium, and it is the image of this star which you see on the screen. It is evident that the rays coming from the negative pole project an image of anything that happens to be in front of it. The discharge, therefore, must come from the pole in straight lines, and does not merely permeate all parts of the tube and fill it with light as it would were the exhaustion less good. Where there is nothing in the way the rays strike the screen and produce phosphorescence, and where there is an obstacle they are obstructed by it, and a shadow is thrown on the screen. I shall have more to say about this shadow presently; I merely now wish to establish the fact that these rays driven from the negative pole produce a shadow.

I must draw your attention to an important experiment connected with these molecular rays, but unfortunately it is a very delicate one, and very difficult to show to many at once; but I hope, if you know beforehand what to look for, you will all be able to see what I wish to show. In this pear-shaped bulb (Fig. 9A) the negative pole (*a*) is at the pointed end. In the middle is a cross (*b*) cut out of sheet aluminium, so that the rays from the negative pole projected along the tube will be partly intercepted by the aluminium cross, and will project an image of it on the hemispherical end of the tube which is phosphorescent. I think you will all now see the shadow of the cross on the end of the bulb (*c*, *d*), and notice that the cross is black on a luminous

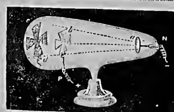

FIG. 9 A.

ground. Now, the rays from the negative pole have been passing by the side of the aluminium cross to produce the shadow; they have been hammering and bombarding the glass till it is appreciably warm, and at the same time they have been producing another effect on that glass—they have deadened its sensibility. The glass has got tired, if I may use the expression, by the enforced phosphorescence. Some change has been produced

FIG. 9 B.

by this bombardment which will prevent the glass from responding easily to additional excitement; but the part that the shadow has fallen on is not tired—it has not been phosphorescing at all, and is perfectly fresh; therefore if I throw this star down—I can easily do so by giving the apparatus a slight jerk, for it has been most ingeniously constructed with a hinge by Mr. Gimingham—and so allow the rays from the negative pole to fall

[1] A short-hand report of a lecture delivered at the Royal Institution on Friday, April 4, 1879. By William Crookes, F.R.S. Continued from p. 231.

85

uninterruptedly on to the end of the bulb, you will suddenly see the black cross (*c*, *d*, Fig. 9B) change to a luminous one (*e*, *f*), because the background is only faintly phosphorescing, whilst the part which had the black shadow on it retains its full phosphorescent power. The luminous cross is now dying out. This is a most delicate and venturous experiment, and I am fortunate in having succeeded so well, for it is one that cannot be rehearsed. After resting for a time the glass seems to partly recover its power of phosphorescing, but it is never so good as it was at first.

We have, therefore, found an important fact connected with

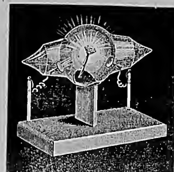

FIG. 10.

this phosphorescence. Something is projected from the negative pole which has the power of hammering away at the glass in front of it, in such a way as to cause it not only to vibrate and become temporarily luminous while the discharge is going on, but to produce an impression upon the glass which is permanent. The explanation which has gradually evolved itself from this series of experiments is this:—The exhaustion in these tubes is so high that the dark space, as I showed you at the commencement of this lecture, that extended round the negative pole, has widened out till it entirely fills the tube. By great rarefaction the mean free path has become so long that the hits in a given

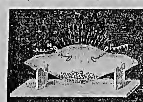

FIG. 11.

time may be disregarded in comparison to the misses, and the average molecule is now allowed to obey its own motions or laws without interference. The mean free path is in fact comparable to the dimensions of the vessel, and we have no longer to deal with a *continuous* portion of matter, as we should were the tubes less highly exhausted, but we must here contemplate the molecules *individually*. At first this was only a convenient working hypothesis. Long-continued experiment then raised this provisional hypothesis almost to the dignity of a theory, and now the general opinion is that this theory gives a fairly correct explanation of the facts. In these highly exhausted vessels the mean free path of the residual molecules of gas is so long that they are able to drive across from the pole to the other side of the tube with comparatively few collisions. The negatively electrified molecules of the gaseous residue in the tube therefore dash against anything that is in front, and cast shadows of obstacles just as if they were rays of light. Where they strike the glass they are stopped, and the production of light accompanies this sudden arrest of velocity.

Other substances besides English, German, and uranian glass, and Becquerel's luminous sulphides are also phosphorescent. I think, without exception, the diamond is the most sensitive substance I have yet met for ready and brilliant phosphorescence. I have here a tube, similar to those already exhibited, containing a mica screen painted with powdered diamond, and when I turn on the coil, the brilliant blue phosphorescence of the diamond can be seen, quite overpowering the green phosphorescence of the glass. Here, again, is a very curious diamond, which I was fortunate enough to meet with a short time ago. By daylight it is green, produced, I fancy, by an internal fluorescence. The diamond is mounted in the centre of this exhausted bulb (Fig. 10), and the negative discharge will be directed on it from below upwards. On darkening the theatre you see the diamond shines with as much light as a candle, phosphorescing of a bright green.

In this other bulb is a remarkable collection of crystals of diamonds, which have been lent me by Prof. Maskelyne. When I pass the discharge over them I am afraid you will only be able to see a few points of light, but if you will examine them after the lecture, you will see them phosphoresce with a most brilliant series of colours—blue, apricot, red, yellowish green, orange, and pale green.

Next to the diamond the ruby is one of the most remarkable stones for phosphorescing. In this tube (Fig. 11) is a collection of ruby pebbles, for the loan of which I am indebted to my friend Mr. Blogg, of the firm of Blogg and Martin, who placed a small sackful at my disposal. As soon as I turn on the induction spark you will see these rubies shining with a brilliant rich red colour, as if they were glowing hot. Now the ruby is nothing but crystallised alumina with a little colouring-matter, and it became of great interest to ascertain whether the artificial ruby made by M. Feil, of Paris, would glow in the same manner. I had simply to make my wants known to M. Feil, and he immediately sent me a box containing artificial rubies and crystals of alumina of all sizes, and from those I have selected the mass in this tube which I now place under the discharge: they phosphoresce of the same rich red colour as the natural ruby. It scarcely matters what colour the ruby is, to begin with. In this tube of natural rubies there are stones of all colours—the deep red ruby and the pale pink ruby. There are some so pale as to be almost colourless, and some of the highly-prized tint of pigeon's blood; but in the vacuum under the negative discharge they all phosphoresce with about the same colour.

As I have just mentioned, the ruby is crystallised alumina. In a paper published twenty years ago by Ed. Becquerel,[1] I find that he describes the appearance of alumina as glowing with a rich red colour in the phosphoroscope (an instrument by which the duration of phosphorescence in the sunlight can be examined). Here is some chemically pure precipitated alumina which I have prepared in the most careful manner. It has been heated to whiteness, and you see it glows with the rich red colour which is supposed to be characteristic of alumina. The mineral known as corundum is a colourless variety of crystallised alumina. Under the negative discharge in a vacuum, corundum phosphoresces of a rose-pink colour. There is another curious fact in which I think chemists will feel interested. The sapphire is also crystallised alumina, just the same as the ruby. The ruby has a little colouring-matter in it, giving it a red colour; the sapphire has a colouring-matter which gives it a blue colour, whilst corundum is white. I have here in a tube a very fine crystal of sapphire, and, when I pass the discharge over it, it gives alternate bands of red and green. The red we can easily identify with the glow of alumina; but what is the green? If alumina is precipitated and purified as carefully as in the case I have just mentioned, but in a somewhat different manner, it is found to glow with a rich green colour. Here are the two specimens of alumina in tubes, side by side. Chemists would say that there was no difference between one and the other; but I connect them with the induction-coil, and you see that one glows with a bright green colour, whilst the other glows with a rich red colour. Here is a fine specimen of chemically pure alumina,

[1] *Annales de Chimie et de Physique*, 3rd series, vol. lvii. p. 50, 1859.

86

87

violently from the negative pole. If I place something in front of these molecules, they show the force of impact by the heat which is produced. Can I make this mechanical action evident in a more direct way? Nothing is simpler. I have only to put some easily moving object in the line of discharge in order to get a powerful mechanical action. Mr. Gimingham, with great

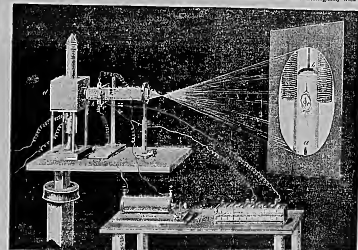

FIG. 16.

skill, has constructed a piece of apparatus which I will presently put in the electric lantern, so that all will be able to see its action. But first I will explain the construction by means of this diagram (Fig. 19). The negative pole (*a*, *b*) is in the form of a very shallow cup. In front of the cup is a mica screen

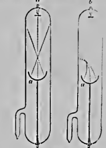

FIG. 17.

(*c*, *d*), wide enough to intercept nearly all the molecular rays coming from the negative pole. Behind this screen is a mica wheel (*e*, *f*) with a series of vanes, making a sort of paddle-wheel of it. So arranged, the molecular stream from the pole *a b* will nearly all be cut off from the wheel, and what escapes over and under the screen will hit the vanes equally, and will not produce any movement. I now put a magnet, *g*, over the tube, so as to

FIG. 18.

deflect the stream over or under the obstacle *c d*, and the result will be rapid motion in one or the other direction, according to

MOLECULAR PHYSICS IN HIGH VACUA[1]

WHEN I was asked, a month or two ago, to illustrate in this theatre some of my recent researches on molecular physics in high vacua, I exclaimed, "How is it possible to bring such a subject worthily before a Royal Institution audience when none of the experiments can be seen more than three feet off?" If to-night I am fortunate enough to show all the experiments to those who are not far distant, and if I succeed in making most of them visible at the far end of the theatre, such a success will be entirely due to the great kindness of your late secretary, Mr. Spottiswoode, who has placed at my disposal his magnificent induction-coil—not only for this lecture, but for some weeks past in my own laboratory—thus enabling me to prepare apparatus and vacuum tubes on a scale so large as to relieve me of all anxiety so far as the experimental illustrations are concerned.

Before describing the special researches in molecular physics which I propose to illustrate this evening, it is necessary to give a brief outline of one small department of the modern theory of the constitution of gases. It is not easy to make clear the kinetic theory, but I will try to simplify it in this way:—Imagine that I have in a large box a swarm of bees, each bee independent of its fellow, flying about in all manner of directions and with very different velocities. The bees are so crowded that they can only fly a very short distance without coming into contact with one another or with the sides of the box. As they are constantly in collision, so they rebound from each other with altered velocities and in different directions, and when these collisions take place against the sides of the box pressure is produced. If I take some of the bees out of the box, the distance which each individual bee will be able to fly before it comes into contact with its neighbour will be greater than when the box was full of bees; and if I remove a great many of the bees I increase to a considerable extent the average distance that each can fly without a collision. This distance I will call the bee's *mean free path*. When the bees are numerous the mean free path is very short; when the bees are few the mean free path will be longer, the length being inversely proportional to the number of bees present. Let us now imagine a loose diaphragm to be introduced in the centre of the box, so as to divide the number of bees equally. The same number of bees being on each side, the impacts on the diaphragm will be equal; and the mean speed of the bees being the same, the pressure will be identical on each side of the diaphragm, and it will not move.

Let me now warm one side of this division so as to let it communicate extra energy to a bee when it touches it. As before, a bee will strike the diaphragm with its normal mean velocity, but will be driven back with extra velocity, the reaction producing an increase of pressure on the diaphragm. It will be found, however, that although the diaphragm is free to move, the extra strength of the recoil on the warm side does not produce any motion. This at first sight seems contrary to the law of action and reaction being equal. The explanation is not difficult to understand. The bees which fly away from the diaphragm have drawn energy from it, and therefore move quicker than those which are coming towards it; they beat back the crowd to a greater distance, and keep a greater number from striking the diaphragm. Near to the heated side of the diaphragm the density is less than the average, while beyond the free path the density is above the average, and this greater crowding extends to all other parts of the box. Thus it happens that the extra energy of the impacts against the warm side of the diaphragm is exactly compensated by the increased number of impacts on the cool side. In spite therefore of the increased activity communicated to a portion of the bees, the pressure on the two sides of the diaphragm will remain the same. This represents what occurs when the extent of the box containing the bees is so great, compared with the mean free path, that the abrupt change in the velocities of those bees which rebound from the walls of the box produces only an insensible influence on the motions of bees at so great a distance as the diaphragm.

I will next ask you to imagine that I am gradually removing bees from our box, still keeping the diaphragm warm on one side. The bees getting fewer the collisions will become less frequent, and the distance each bee can fly before striking its neighbour will get longer and longer, and the crowding in front of them will grow less and less. The compensation will also diminish, and the warmed side of the diaphragm will have a tendency to be beaten back. A point will at last be reached on the warm side, when the mean free path of the bees will be long enough to admit of their dashing right across from the diaphragm to the side of the box, without meeting more than a certain number of in-coming bees in their flight. In this case the bees will no longer fly quite in the same direction as before. They will now fly less sideways, and more forwards and backwards between the heated face of the diaphragm and the opposed wall of the box. Because of this preponderating motion, and also because they will thereby less effectually keep back bees crowding in from the sides, there will now be a greater proportionate pressure both on the hot face of the diaphragm and on that part of the box which is in front of it. Hence the pressure on the hot side will now exceed that on the cool side of the diaphragm, which will consequently have a backward movement communicated to it.

FIG. 1.

I may diminish the size of the bees as much as I like, and by correspondingly increasing their number the mean free path will remain the same. Instead of bees let me call them molecules, and instead of having a few hundreds or thousands in the box let me have millions and billions and trillions; and if we also diminish the mean free path to a considerable extent, we get a rough outline of the kinetic theory of gases. (I may just mention that the mean free path of the molecules in air, at the ordinary pressure, is the ten-thousandth of a millimetre.)

Three years ago I had the honour of bringing before you the results of some researches on the radiometer. Let me now take up the subject where I then left off. I have here two radiometers which have been rotating before you under the influence of a strong light shining upon them.

The explanation of the movement of the radiometer is this—the light, or the total bundle of rays included in the term "light," falling upon the blackened side of the vanes, becomes absorbed, and thereby raises the temperature of the black side: this causes extra excitement of the air molecules which come in contact with it, and pressure is produced, causing the fly of the radiometer to turn round.

I have long believed that a well-known appearance observed in vacuum tubes is closely related to the phenomena of the mean

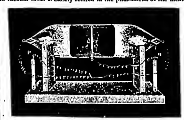

FIG. 2.

free path of the molecules. When the negative pole is examined while the discharge from an induction coil is passing through an exhausted tube, a dark space is seen to surround it. This dark space is found to increase and diminish as the vacuum is varied, in the same way that the ideal layer of molecular pressure in the radiometer increases and diminishes. As the one is perceived by the mind's eye to get greater, so the other is seen by the bodily eye to increase in size. If the vacuum is insufficient to permit the radiometer to turn, the passage of electricity shows

[1] A short-hand report of a lecture delivered at the Royal Institution on Friday, April 4, 1879. By William Crookes, F.R.S. Contributed by the author.

that the "dark space" has shrunk to small dimensions. It is a natural inference that the dark space is the mean free path of the molecules of the residual gas.

The radiometer which has just been turning under the influence of the lime-light is not of the ordinary kind. Fig. 1 will explain its construction.

It is similar to an ordinary radiometer with aluminium disks for vanes, each disk coated on one side with a film of mica. The fly is supported by a hard steel instead of glass cup, and the needle point on which it works is connected by means of a wire with a platinum terminal sealed into the glass. At the top of the radiometer bulb a second terminal is sealed in. The radiometer can therefore be connected with an induction-coil, the movable fly being made the negative pole.

As soon as the pressure is reduced to a few millims. of mercury, a halo of velvety violet light forms on the metallic side of the vanes, the mica side remaining dark. As the pressure diminishes, a dark space is seen to separate the violet halo from the metal. At a pressure of half a millim. this dark space extends to the glass, and positive rotation commences. On continuing the exhaustion the dark space further widens out and appears to flatten itself against the glass, when the rotation becomes very rapid.

You perceive a dark space behind each vane and moving round with it. In the first experiment, radiation from the lime-light falling on the metallic sides of the vanes, produced a layer of molecular pressure which drove the fly round; so here the induction-current has produced molecular excitement at the surface of the vanes forming the negative pole, extending up to the side of the glass.

When the negative pole is in rapid rotation it is not easy to see this dark space, so I have arranged a tube in which the dark space will be visible to all present. The tube, as you will see by the diagram (Fig. 2), has a pole in the centre in the form of a metal disk, and other poles at each end. The centre pole is made negative, and the two end poles connected together are made the positive terminal. The dark space will be in the centre. When the exhaustion is not very great the dark space extends only a little distance on each side of the negative pole in the centre. When the exhaustion is very good, as it is in the tube before you, and I turn on the coil, the dark space is seen to extend for about two inches on each side of the pole.

Here, then, we see the induction spark actually illuminating the lines of molecular pressure caused by the excitement of the negative pole. The thickness of this dark space—nearly two inches—is the measure of the mean free path between successive collisions of the molecules of the residual gas. The extra velocity with which the negatively electrified molecules rebound from the excited pole keeps back the more slowly moving molecules which are advancing towards that pole. The conflict occurs at the boundary of the dark space, where the luminous margin bears witness to the energy of the discharge.

I will endeavour to throw on the screen an illustration of this dark space. A stream of water falls from a small jet on to a horizontal plate of glass. The water spreads over the plate and forms a thin film. The jet of water in the centre, from the velocity of its fall, drives the film of water before it on all sides, raising it into a ring-shaped heap. As I diminish the force of the jet the ring contracts; this is equivalent to the exhaustion getting less. When I increase the force of water the ring expands in size, the effect being analogous to an increase of exhaustion in my tubes. The extra velocity of the falling particles of water drives the in-coming particles of water before them, and raises a ridge round the side which exactly represents the luminous halo to the dark space to be seen in this tube.

If, instead of a flat disk, a metal cup is used for the negative pole, the successive appearances on exhausting the tube are somewhat different. The velvety violet halo forms over each side of the cup. On increasing the exhaustion the dark space widens out, retaining almost exactly the shape of the cup. The bright margin of the dark space becomes concentrated at the concave side of the cup to a luminous focus, and widens out at the convex side. When the dark space is very much larger than the cup, its outline forms an irregular ellipsoid drawn in towards the focal point. Inside the luminous boundary a dark violet light can be seen converging to a focus, and, as the rays diverge on the other side of the focus, spreading beyond the margin of the dark space; the whole appearance being strikingly similar to the rays of the sun reflected from a concave mirror through a foggy atmosphere. This proves a somewhat important point; it shows that the molecules thrown off the excited negative pole leave it in a direction almost normal to the surface.

I can illustrate this property of the molecular rays by an experiment. This diagram (Fig. 3) is a representation of the tube which is before you. It contains, as a negative pole, a hemi-cylinder (*a*) of polished aluminium. This is connected with a fine copper wire, *b*, ending at the platinum terminal, *c*.

FIG. 3.

At the upper end of the tube is another terminal, *d*. The induction-coil is connected so that the hemi-cylinder is negative and the upper pole positive, and when exhausted to a sufficient extent, as is the case with this tube, the projection of the molecular rays to a focus is very beautifully shown. The rays are driven from the hemi-cylinder in a direction normal to its surface; they come to a focus and then diverge, tracing their path in brilliant green phosphorescence on the surface of the glass.

You will notice that the rays which project from the negative pole and cross in the centre have a bright green appearance; that colour is entirely due to the phosphorescence of the glass. At a very high exhaustion the phenomena noticed in ordinary vacuum tubes when the induction spark passes through them—an appearance of cloudy luminosity and of stratifications—disappears entirely. No cloud or fog whatever is seen in the body of the tube, and with such a vacuum as I am working with in these experiments—about a millionth part of an atmosphere—the inner surface of the glass glows with a rich green phosphorescence, the intensity of colour varying with the perfection of the vacuum. It scarcely begins to show much before the 800,000th of an atmosphere. At about a millionth of an atmosphere the phosphorescence is very strong, and after that it begins to diminish

FIG. 4.

until there are not enough molecules left to allow the spark to pass.[1]

I have here a tube which will serve to illustrate the dependence of the green phosphorescence of the glass on the degree of perfection of the vacuum (Fig. 4). The two poles are at *a* and

NOUVELLES RECHERCHES DE M. CROOKES

SUR LE RADIOMÈTRE.

M. Crookes a montré que le mouvement du radiomètre est dû à la présence de gaz résiduel. Il a étudié dernièrement la répulsion exercée par la radiation d'une lampe sur des disques de mica et de moelle de sureau recouverts de diverses poudres ou précipités chimiques, et suspendus dans le vide d'un appareil de torsion.

Le tube de verre horizontal *a b* (fig. 1) contient un fléau en paille, à la fois léger et suffisamment rigide. Le fil de torsion *c d*, en flint-glass, est fixé

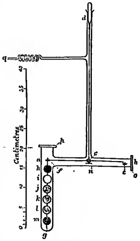

Fig. 1.

en *d* à un bouchon à l'émeri; pour avoir une fermeture hermétique, on coule autour du bouchon un mastic formé de deux parties de résine et trois de cire d'abeilles. En *c* est un miroir de verre argenté; en *e* une petite cuvette destinée à recevoir les contre-poids des disques suspendus à l'autre extrémité. Ces disques, au nombre de six, sont collés sur une tige de verre rigide avec un peu de mastic, et cette tige est ajustée à l'extrémité du fléau au moyen d'une lame d'aluminium. Le premier de ces disques, *h*, est toujours en moelle recouverte de noir de fumée : les autres sont changés à chaque expérience. Un petit aimant permet d'amener le fléau au 0° sans enlever le bouchon *d*. Deux glaces sont mastiquées en *o* et *p*; on les enlève pour changer les disques; on fait le vide dans

l'appareil par le tube *g* qui communique avec une machine pneumatique à mercure.

CONTRIBUTIONS TO MOLECULAR PHYSICS IN HIGH VACUA.*

Engl Mechanic July Aug 1 1879

THIS paper is a continuation of one "On the Illumination of Lines of Molecular Pressure, and the Trajectory of Molecules" (p. 383, Vol. XXVIII.). The author has further examined the action of the molecular rays electrically projected from the negative pole in very highly exhausted tubes, and finds that the green phosphorescence of the glass (by means of which the presence of the molecular rays is manifested) does not take place close to the negative pole. Within the dark space there is absolutely no phosphorescence; at very high exhaustions the luminous boundary of the dark space disappears, and now the phosphorescence extends all over the sensitive surface. Assuming that the phosphorescence is due either directly or indirectly to the impact of the molecules on the phosphorescent surface, it is reasonable to suppose that a certain velocity is required to produce the effect. The author adduces arguments to show that within the dark space, at a moderate exhaustion, the velocity does not accumulate to a sufficient extent to produce phosphorescence, but at higher exhaustions the mean free path is long enough to allow the molecules to get up sufficient speed to excite phosphorescence. At a very high exhaustion there are fewer collisions, and the initial speed of the molecules close to the negative pole not being thereby reduced, phosphorescence takes place close to the pole.

Experiments are described in which a pole folded into corrugations is used at one end of a tube, the pole at the other end being flat, set obliquely to the axis of the tube, and having a plate of mica in front pierced with a hole opposite the centre of the pole. The questions which this apparatus was designed to answer are: (1) Will there be two sets of molecular projections from the corrugated pole when made negative, one perpendicular to each facet, or will the projection be perpendicular to the electrode as a whole, i.e., along the axis of the tube? (2) Will the molecular rays from the oblique flat pole, when this is made negative, issue through the aperture of the screen along the axis of the tube, i.e., direct to the positive pole, or will they leave the pole normal to the surface and strike the glass on its side? With the corrugated pole experiment shows that at high exhaustions molecular rays are projected from each facet to the inner surface of the tube, where they excite phosphorescence, and form portions of ellipses by the intersection of the planes of molecular rays with the cylindrical tube. When the oblique flat pole is made negative, a stream of molecules shoots from it nearly normal to its surface, and those which pass through the hole in the plate of mica strike the side of the tube, forming an oval patch of a green colour.

The oval patch in this apparatus happens to fall on a portion of the glass which has previously had its phosphorescence excited by the molecular discharge from the other corrugated pole. The phosphorescence from this pole is always more intense than that from the flat pole, and the glass, after having been excited by the energetic bombardment, ceases to respond readily to the more feeble excitement from the flat pole. The effect, therefore, is that, when the oval spot appears, it has a dark band across it where the phosphorescence from the other pole has been taking place. The glass recovers its phosphorescent power to some extent after rest.

In this apparatus a shifting of the line of molecular discharge is noticed. If the coil is stopped and then set going repeatedly, always keeping the oblique pole negative, the spot of green light occurs on the glass at the spot where it should come supposing the discharge were normal to the surface of the pole. But if once the flat pole is made positive, the next time it is made negative the spot of light appears nearer the axis of the tube, and instantly shifts to its normal position, where it remains so long as the pole is made negative. There seems no limit to the number of times this experiment can be repeated.

A suggestion having been made by Professor Stokes that a third, idle, pole should be introduced between the negative and positive electrodes, experiments are described with an apparatus constructed accordingly. The potential of the idle poles (of which there are two) at low exhaustions is very feebly positive; as the exhaustion gets better the positive potential increases, and at a vacuum so good as to be almost non-conducting, the positive potential of the idle poles is at its greatest. The result is that an idle pole in the direct line of fire between the positive and negative poles, and consequently receiving the full impact of the molecules driven from the negative pole, has a strong positive potential.

* Abstract of a Paper read before the Royal Society.

It is found that when the shadow of an idle pole is projected on a phosphorescent screen the trajectory of the molecules suffers deflection when the idle pole is suddenly uninsulated by connecting it with earth. The same result is produced by connecting the idle pole with the negative wire through a very high resistance, such as a piece of wet string, instead of connecting it with earth. A tube, which has already been described in a paper read before the Royal Society on December 5th last, is used to illustrate this deflection. The shadow of an aluminium star is projected on a phosphorescent screen. So long as the metal star is insulated the shadow remains sharp, but on uninsulating the star by connecting it with an earth wire the shadow widens out, forming a tolerably well-defined penumbra outside the original shadow, which can still be seen unchanged in size and intensity. On removing the earth connection, the penumbra disappears, the umbra remaining as before.

It is also found that the shadow of the star is sharply projected when it is made the positive pole, the negative pole remaining unchanged.

These experiments are explained by the results just mentioned, that the idle pole, the shadow of which is cast by the negative pole, has strong positive potential. The stream of molecules must be assumed to have negative potential; when they actually strike the idle pole they are arrested, but those which graze the edge are attracted inwards by the positive potential and form the umbra. When the idle pole is connected with earth, its potential would become zero were the discharge to cease; but inasmuch as a constant supply of positive electricity is kept up from the passage of the current, we must assume that the potential of the idle pole is still sufficient to more than neutralise the negative charge which the impinging molecules would give it. The effect, therefore, of alternately uninsulating and insulating the idle pole is to vary its positive potential between considerable limits, and consequently its attractive action on the negative molecules which graze its edge. The result is a wide or a narrow shadow, according to circumstances.

After a definite shadow is produced, it is found that increasing the exhaustion makes very little change in the umbra, but it causes the penumbra to increase greatly in size. Experiments recorded in the Paper already quoted have proved that the velocity of the molecules is greater as the vacuum gets higher, and consequently the trajectory of the molecules under deflecting action, whether of a magnet or of an insulated idle pole, is flatter at high than at low vacua.

An experiment is next described, having for its object to ascertain whether two parallel molecular rays from two adjacent negative poles attract or repel each other. It is considered that if the stream carries an electric current, attraction should ensue, but if they are simply streams of similarly electrified bodies, the result would be repulsion. Experiment proves that the latter alternative happens, lateral repulsion taking place between two streams moving in the same direction.

Many experiments are given to illustrate the law of action of magnets on the molecular stream, but the results are of too complicated a character to bear condensation without the diagrams accompanying the original paper.

The molecular stream is sufficiently sensitive to show appreciable deflection by the magnetism of the earth.

The author, after numerous experiments, has succeeded in obtaining continuous rotation of the molecular stream under the influence of a magnet, analogous to the well-known rotation at lower exhaustions. Comparative experiments are given with a "high vacuum" tube, where no luminous gas is visible, but only green phosphorescence on the surface of the glass, and a "low vacuum" tube, in which the induction spark passes in the form of a luminous band of light joining the two poles. These two tubes are mounted over similar electro-magnets, the direction of discharge being in a line with the axis of the magnet. Numerous experiments, the details of which are given in the paper, show that the law is not the same at high as at low exhaustions. At high exhaustions the magnet causes the molecular rays to rotate in the same direction, whether they are coming towards the magnet or going from it, the direction of rotation being entirely governed by the magnetic pole presented to the stream. The north pole rotates the molecular discharge in a direct sense, independent of the direction in which the induction current passes. The direction of rotation impressed on the molecules by a magnetic pole is opposite to the direction of the electric current circulating round the magnet. These results offer an additional proof that the stream of molecules driven from the negative pole in high vacua do not carry an electric current in the ordinary sense of the term.

The author, after giving details of experiments in which platinum and glass are fused in the focus of converging molecular rays projected from a concave pole, describes observations with the spectroscope, which show that glass obstinately retains at even a red heat a compound of hydrogen—probably water—which is only driven completely off by fusion. The permanent deadening of the phosphorescence of glass is shown by projecting the shadow of a metal cross on the end of a bulb for a considerable time. On suddenly removing the cross, its image remains visible, bright upon a dark ground.

One of the most striking of the phenomena attending this research is the remarkable power which the molecular rays in a high vacuum have of causing phosphorescence in bodies on which they fall. Substances known to be phosphorescent under ordinary circumstances shine with great splendour when subjected to the negative discharge in a high vacuum. Thus Becquerel's luminous sulphide of calcium has been found invaluable in this research for the preparation of phosphorescent screens whereon to trace the paths and trajectories of the molecules. It shines with a bright blue-violet light, and when on a surface of several square inches is sufficient to faintly light a room.

The only body which the author has yet met with which surpasses the luminous sulphides, both in brilliancy and variety of colour, is the diamond. Most diamonds from South Africa phosphoresce with a blue light. Diamonds from other localities shine with different colours, such as bright blue, apricot, pale blue, red, yellowish green, orange, and pale green. One very beautiful diamond in the author's collection gives almost as much light as a candle when phosphorescing in a good vacuum.

Next to the diamond, alumina and its compounds are the most strikingly phosphorescent. The ruby glows with a rich full red, and it is of little consequence what degree of colour the stone possesses naturally, the colour of the phosphorescence is nearly the same in all cases; chemically prepared and strongly ignited alumina phosphoresces with as rich a red glow as the ruby. The phosphorescent glow does not, therefore, depend on the colouring matter. E. Becquerel has shown by experiments with his phosphoroscope that alumina and many of its compounds phosphoresce of a red colour after insolation.

Nothing can be more beautiful than the effect presented by a mass of rough rubies when glowing in a vacuum: they shine as if they were red hot, and the illumination effect is almost equal to that of the diamond under similar circumstances. Masses of artificial ruby in crystals prepared by M. Ch. Feil, behave in the vacuum like the natural ruby.

In the spectroscope the alumina-glow shows one intense and sharp red line less refrangible than the line B, and a faint continuous spectrum ending at about B. The wave-length of the red line is 6895.

The paper concludes with some notes by Professor Maskelyne, on the connection between molecular phosphorescence and crystalline structure.

The crystals experimented on have been the diamond, emerald, beryl, sapphire, ruby, quartz, phenakite, tinstone, hyacinth (zircon), tourmaline, andalusite, enstatite, minerals of the augite class, apatite, topaz, chrysoberyl, peridot, garnet, and boracite. Of these, the only crystals which give out light are diamond, ruby, emerald, sapphire, tinstone, and hyacinth. The light from emerald is crimson, and is polarised, apparently completely, in a plane perpendicular to the axis. Sapphire gives out a bluish-grey and a red light polarised in a plane perpendicular to the axis. The ruby light exhibits no marked distinction in the plane of its polarisation.

Among positive crystals tinstone glows with a fine yellow light, polarised in a plane parallel to the axis of the crystal. So far, the experiments accord with the quicker vibrations being those called into play, and therefore in a negative crystal the extraordinary, and in a positive crystal the ordinary, is the ray evoked. Hyacinth, however, introduces a new phenomenon, being dichroic, the colours, in three different crystals, being pale, pink and lavender—blue, pale blue and deep violet, and yellow and deep violet-blue, polarised in opposite planes. The only conclusion arrived at is, that the rays whose direction of vibration corresponds to the direction of maximum optical elasticity in the crystal, are always originated where any light is given out. As yet, however, the induction on which so remarkable a principle is suggested, cannot be considered sufficiently extended to justify that principle being accepted as other than probable.

AIR-PUMPS.

" Kravogl's air-pump contains a hollow glass cylinder AB opening at the upper end, and surmounted by a kind of funnel. The piston is of the same shape as the cylinder, and is covered with a layer of mercury, whose depth over the point of the piston is about $\frac{1}{50}$th of an inch when the piston is at the bottom of its stroke, but is nearly an inch when the piston rises and fills the funnel-shaped cavity in which the pump-barrel terminates. A small interval, filled by the liquid, is left between the barrel and the piston; but at the bottom of the barrel the piston passes through a leather box carefully made, so as to be perfectly air-tight.

" The air from the receiver passes through the lateral opening c; it is driven before the mercury into the funnel above. With the air passes a certain quantity of mercury, which is detained by a steel valve, c, at the narrowest part of the funnel. This valve

IRON July 26 1879

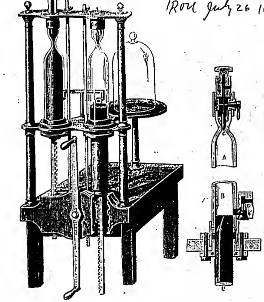

Fig. 115. Kravogl's Air Pump.

rises automatically when the surface of the mercury is at a distance of about half an inch from the funnel, and falls back into its former position when the piston is at the end of its upward stroke. In the downward stroke, when the mercury is again half an inch from the funnel, the valve opens again and allows a portion of the mercury to pass.

" The effect of this arrangement is easily understood; there is no 'untraversed space,' the presence of the mercury above and around the piston causes a very complete fit, and excludes the external air; and hence the machine, when well made, is very effective.

" When this is the case, and when the mercury used in the apparatus is perfectly dry, a vacuum of about $\frac{1}{250}$th of an inch can be obtained. The dryness of the mercury is a very important condition, for at ordinary temperatures the elastic force of the vapour of water has a very sensible value. If we wish to employ the full powers of the machine, we must have, between the vessel to be exhausted of air and the pump-barrel, a desiccating apparatus.

" The arrangement of the valve c is peculiar. It is of a conical form, so as, in its lowest position, to permit the passage of air coming from the receiver. Its ascent is produced by the pressure of the mercury, which forces it against the conical extremity of the passage, and the liquid is thus prevented from escaping.

" The figure represents a double-barrelled machine analogous to the ordinary air-pump. Besides the pinion working with the racks of the pistons, there is a second smaller pinion, not shown in the figure, which governs the movements of the valves c. All the parts of this machine, as the stop-cocks, valves, pipes, &c., must be of steel

over

to avoid the action which the mercury would have upon any other metal."

"Geissler, of Bonn, has invented a mercurial air-pump, in which the vacuum is produced by communication of the receiver with the Torricellian vacuum. Fig. 146 represents this machine as constructed by Alvergniat. It consists of a vertical tube, which serves as a barometric tube, and communicates at the bottom, by means of a caoutchouc tube, with a globe which serves as the cistern.

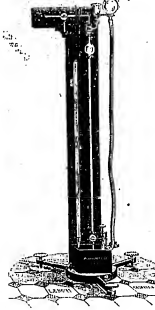

Fig. 146. Geissler's Machine.

"At the top of the tube is a three-way stop-cock, by which communication can be established either with the receiver to the left, or with a funnel to the right, which latter has an ordinary stop-cock at the bottom. By means of another stop-cock on the left, communication with the receiver can be opened or closed. These stop-cocks are made entirely of glass. The machine works in the following manner:—Communication being established with the funnel, the globe which serves as cistern is raised, and placed, as shown in the figure, at a higher level than the stop-cock of the funnel. By the law of equilibrium in communicating vessels, the mercury fills the barometric tube, the neck of the funnel, and part of the funnel itself. If the communication between the funnel and tube be now stopped, and the globe lowered, a Torricellian vacuum is produced in the upper part of the vertical tube.

"Communication is now opened with the receiver; the air rushes into the vacuum, and the column of mercury falls a little. Communication is now stopped between the tube and receiver, and opened between the tube and the funnel, the simple stop-cock of the funnel being, however, left shut. If at this moment the globe is replaced in the position shown in the figure, the air endeavours to escape by the funnel, and it is easy to allow it to do so. Thus, a part of the air of the receiver has been removed, and the apparatus is in the same position as at the beginning. The operation described is equivalent to a stroke of the piston in the ordinary machine, and this process must be repeated till the receiver be exhausted.

"As the only mechanical parts of this machine are glass stop-cocks, which are now executed with great perfection, it is capable of giving good results. With dry mercury a vacuum of $\frac{1}{250}$th of an inch may very easily be obtained. The working of the machine, however, is inconvenient, and becomes exceedingly laborious when the receiver is large. It is therefore employed directly only for producing a vacuum in very small vessels; when the spaces to be exhausted of air are at all large, the operation is begun with the ordinary machine, and the mercurial air-pump is only employed to render the vacuum thus obtained more perfect."

Sc. Am. S. — Aug 9 1879

ELECTRIC DISCHARGES IN RAREFIED GASES.

Messrs. De La Rue and Müller, in the researches which they have carried on during three and a half years, have contributed facts of the highest value toward the solution of the problem presented by the beautiful phenomenon of stratification produced by electric discharges in vacuum tubes. The results of their labors are given in full in the *Philosophical Transactions*.

The authors state that there is a serious trouble connected with the study of the discharge in rarefied gases, for, after a very short time, the tubes completely and permanently change, so as no longer to present the splendid stratification witnessed on a first trial. We believe these changes occur much more rapidly with the battery in consequence of the greater amount of current than with the induction coil; but the fact appears to have been well known to Dr. Geissler, of Bonn, who, on the occasion of a visit to our laboratory, brought with him some tubes through which no current had previously passed (virgin tubes, as he called them), which presented most beautiful phenomena lost for ever after too brief a period.

A cyanogen tube, for example, when first connected with the battery, presented strata which completely filled the tube without leaving a dark space near the negative, some threading themselves on it, but after a few seconds the strata widened out as on the right hand figure, then other changes occurred, and the first phases have never been reproduced.

After spending much time in experiments with tubes prepared for us by Dr. Geissler, Messrs. Alvergniat Frères, of Paris, and Mr. Hicks, of Hatton Garden, with the vexation of finding that we could not often enough repeat our experiments, we ultimately came to the conclusion to have others made, but not exhausted, and to perform ourselves the charging and exhaustion. The tubes we usually employ have a glass stop-cock fitted to them at each end; they are 32 inches long, and from 1·75 to 2 inches in diameter; the terminals are of aluminum, and about 29 inches apart, one being a ring, the other a wire bent at a right angle, so as to point in the direction of the axis of the tube, for we have found that the phenomena vary according as the ring or wire is made positive.

These we exhaust and fill with any gas we may wish to experiment with, and gradually exhaust again, noting the phenomena presented at different pressures, with different potentials, and with different amounts of current. We refill and exhaust the tube again and again, and mostly obtain, under the same conditions, as nearly as possible the same phenomena, of which we are careful to make sketches and, if possible, to obtain photographic records.

The apparatus which we have found it advantageous to adopt for the exhaustion of our tubes comprises three means of exhaustion, which are successively employed as the vacuum becomes more perfect. The first is an Alvergniat high-pressure water *trompe* in connection with the high-pressure water main of the West Middlesex Water Company, the head of water being 166 feet; it produces a vacuum to within half an inch (0·47 in. = 12 millims.) of the height of the barometer. The other end of the vacuum tube communicates by means of a Y-piece to both, an Alvergniat mercurial pump, and a Sprengel pump on the left. After the *trompe* has done its work, the Alvergniat is used for rapid exhaustion, and then shut off, leaving the exhaustion to be completed by the Sprengel; we have thus obtained, by the pumps alone, in tubes 32 inches long and 2 inches in diameter, vacua of only 0·032 millimeter pressure, equal to 2·0 millionths of an atmosphere—a vacuum so perfect that the current of 8,040 cells would not pass. The apparatus is in connection with a McLeod gauge, by means of which pressures to 0·00005 mm. can be determined. Besides this gauge the Sprengel and Alvergniat pumps have their own gauges, which read to a millimeter.

Our observations show clearly that discharge through rarefied gases cannot be at all analogous to conduction through metals; for a wire having a given difference of potential between its ends can permit one—and only one—current to pass; whereas from the measurements obtained, it became evident that with a given difference of potential between the terminals of a given vacuum tube currents of strengths varying from 1 to 135 can flow. We are therefore led to the conclusion that the discharge in a vacuum tube does not differ essentially from that in air and other gases at ordinary atmospheric pressures—that it is, in fact, a disruptive discharge.

In every case where the strata are to the eye or rotating-mirror perfectly steady slight deflections of the needle are seen; these generally indicate a resultant direct current

increased, the strata pour in, one after the other, in the most steady and beautiful manner from the positive.

5. A change of current frequently produces an entire change in the color of the strata; for example, in a hydrogen tube from a cobalt blue to a pink. It also changes the spectrum of the strata; moreover, the spectra of the illuminated terminals and the strata differ.

6. If the discharge is irregular and the strata indistinct, an alteration of the amount of current makes the strata distinct and steady. Most frequently a point of steadiness is produced by the careful introduction of external resistance; subsequently the introduction of more resistance produces a new phase of unsteadiness, and still more resistance another phase of steady and distinct stratification.

7. The greatest heat is in the vicinity of the strata. This can be best observed when the tube contains either only one stratum, or a small number separated by a broad interval. There is reason to believe that even in the dark discharge there may be strata, for we have found a development of heat in the middle of a tube in which there was no illumination except on the terminals.

8. Even when the strata are to all appearance, perfectly steady, a pulsation can be detected in the current; but it is not proved that the strata depend upon intermittence.

9. There is no current from a battery through a tube divided by a glass division into two chambers, and the tube can only be illuminated by alternating charges.

10. In the same tube and with the same gas a very great variety of phenomena can be produced by varying the pressure and the current. The luminosities and strata, in their various forms, can be reproduced in the same tube, or in others having similar dimensions.

11. At the same pressure and with the same current the diameter of the tube affects the character of the discharge and the form and closeness of the stratification.

to avoid the action which the mercury would have upon any other metal."

"Geissler, of Bonn, has invented a mercurial air-pump, in which the vacuum is produced by communication of the receiver with the Torricellian vacuum. Fig. 146 represents this machine as constructed by Alvergniat. It consists of a vertical tube, which serves as a barometric tube, and communicates at the bottom, by means of a caoutchouc tube, with a globe which serves as the cistern.

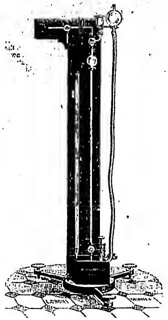

FIG. 146. Geissler's Machine.

"At the top of the tube is a three-way stop-cock, by which communication can be established either with the receiver to the left, or with a funnel to the right, which latter has an ordinary stop-cock at the bottom. By means of another stop-cock on the left, communication with the receiver can be opened or closed. These stop-cocks are made entirely of glass. The machine works in the following manner:—Communication being established with the funnel, the globe which serves as cistern is raised, and placed, as shown in the figure, at a higher level than the stop-cock of the funnel. By the law of equilibrium in communicating vessels, the mercury fills the barometric tube, the neck of the funnel, and part of the funnel itself. If the communication between the funnel and tube be now stopped, and the globe lowered, a Torricellian vacuum is produced in the upper part of the vertical tube.

"Communication is now opened with the receiver; the air rushes into the vacuum, and the column of mercury falls a little. Communication is now stopped between the tube and receiver, and opened between the tube and the funnel, the simple stop-cock of the funnel being, however, left shut. If at this moment the globe is replaced in the position shown in the figure, the air endeavours to escape by the funnel, and it is easy to allow it to do so. Thus, a part of the air of the receiver has been removed, and the apparatus is in the same position as at the beginning. The operation described is equivalent to a stroke of the piston in the ordinary machine, and this process must be repeated till the receiver be exhausted.

"As the only mechanical parts of this machine are glass stop-cocks, which are now executed with great perfection, it is capable of giving good results. With dry mercury a vacuum of $\frac{1}{250}$th of an inch may very easily be obtained. The working of the machine, however, is inconvenient, and becomes exceedingly laborious when the receiver is large. It is therefore employed directly only for producing a vacuum in very small vessels; when the spaces to be exhausted of air are at all large, the operation is begun with the ordinary machine, and the mercurial air-pump is only employed to render the vacuum thus obtained more perfect."

—one being a ring, the other a wire bent at a right angle, so as to point in the direction of the axis of the tube, for we have found that the phenomena vary according as the ring or wire is made positive.

These we exhaust and fill with any gas we may wish to experiment with, and gradually exhaust again, noting the phenomena presented at different pressures, with different potentials, and with different amounts of current. We refill and exhaust the tube again and again, and mostly obtain, under the same conditions, as nearly as possible the same phenomena, of which we are careful to make sketches and, if possible, to obtain photographic records.

The apparatus which we have found it advantageous to adopt for the exhaustion of our tubes comprises three means of exhaustion, which are successively employed as the vacuum becomes more perfect. The first is an Alvergniat high-pressure water *trompe* in connection with the high-pressure water main of the West Middlesex Water Company, the head of water being 100 feet; it produces a vacuum to within half an inch (0·47 in. = 12 millims.) of the height of the barometer. The other end of the vacuum tube communicates by means of a Y-piece to both, an Alvergniat mercurial pump, and a Sprengel pump on the left. After the *trompe* has done its work, the Alvergniat is used for rapid exhaustion, and then shut off; leaving the exhaustion to be completed by the Sprengel; we have thus obtained, by the pumps alone, in tubes 32 inches long and 2 inches in diameter, vacuum of only 0·032 millimeter pressure, equal to 26 millionths of an atmosphere—a vacuum so perfect that the current of 8,040 cells would not pass. The apparatus is in connection with a McLeod gauge, by means of which pressures to 0·00005 mm. can be determined. Besides this gauge the Sprengel and Alvergniat pumps have their own gauges, which read to a millimeter.

Our observations show clearly that discharge through rarefied gases cannot be at all analogous to conduction through metals; for a wire having a given difference of potential between its ends can permit one—and only one—current to pass; whereas from the measurements obtained, it became evident that with a given difference of potential between the terminals of a given vacuum tube currents of strengths varying from 1 to 135 can flow. We are therefore led to the conclusion that the discharge in a vacuum tube does not differ essentially from that in air and other gases at ordinary atmospheric pressures—that it is, in fact, a disruptive discharge.

In every case where the strata are to the eye or rotating mirror perfectly steady slight deflections of the needle are seen; these generally indicate a resultant direct current (break contact), and in the fewer number of cases an inverse current indicating, in the first case, a sudden decrease and slow increase of current through the tube. These deflections, though very manifest, do not amount to more than about three or four divisions of the galvanometer scale, a deflection which indicates a current of only 0·0000000023 W. At the advent or retreat of a stratum at the positive pole there is frequently produced a deviation of 300 divisions, indicating a current of 0·00000001812 W.; before a stratum leaves the positive terminal or dies out on it, there is usually a tremulous motion of that stratum visible to the eye and indicated by rapid pulsations of the galvanometer.

On the suggestion of Prof. Clerk Maxwell we have recently introduced the telephone into the primary current, and also in the secondary current.

In all cases where the condenser was discharging itself gradually through the tube, a low rustling sound was distinctly audible to sensitive ears so long as the stratification remained apparently perfectly steady. When the phase of confused stratification which immediately precedes extinction was reached, the sound in the telephone became very loud and rose in pitch, with some tubes becoming quite shrill. These results, therefore, confirm the conclusion already arrived at from other experiments, namely, that the discharge in vacuum tubes is intermittent; but we do not pretend that they make it manifest that stratification is dependent upon intermittence.

In the course of our experiments, using sometimes 11,000 cells, we have arrived at the following facts:

1. The discharge in a vacuum tube does not differ essentially from that in air and other gases at ordinary atmospheric pressures; it cannot be considered as a current in the ordinary acceptation of the term, but must be of the nature of a disruptive discharge, the molecules of the gas acting as carriers of electrification. The gases in all probability receive impulses in two directions at right angles to each other, that from the negative being the more continuous of the two. Metal is frequently carried from the terminals and is deposited on the inside of the tube, so as to leave a permanent record of the spaces between the strata.

2. As the exhaustion proceeds the potential necessary to cause a current to pass diminishes up to a certain point, whence it again increases, and the strata thicken and diminish in number, until a point is reached at which, notwithstanding the high electromotive force available, no discharge through the residual gas can be detected. Thus, when one pole of a battery of 8,040 cells was led to one of the terminals of the tube, which has a radiometer attached to it, the other terminal of the tube, distant only 0·1 inch, being connected through a sensitive Thomson galvanometer to the other pole of the battery (earth), the current observed was not greater than that which was found to be due to conduction over and through the glass. Although no current passed, the leading wires acting inductively stopped the motion of the radiometer, as has been observed by Sir William Grove.

3. All strata have their origin at the positive pole. Thus, in a given tube, with a certain gas, there is produced at a certain pressure, in the first instance, only one luminosity which forms on the positive terminal; then, as the exhaustion is gradually carried further, it detaches itself, moving toward the negative, and being followed by other luminosities, which gradually increase in number up to a certain point.

4. With the same potential the phenomena vary irregularly with the amount of current. Sometimes, as the current is increased, the number of strata in certain tubes increases, and as it is diminished their number decreases; but with other tubes the number of strata frequently increases with a diminution of current. If the source of the current is a charged condenser, the flow being from one of its plates through resistances and the tube to the other, then, as the potential of the condenser falls and the current diminishes, the number of strata alters; if the strata diminish in number with the fall of potential, then the stratum nearest the positive wire disappears on it, the next then follows and disappears, and so on with others; if, on the other hand, the charge of the condenser is very gradually

increased, the strata pour in, one after the other, in the most steady and beautiful manner from the positive.

5. A change of current frequently produces an entire change in the color of the strata; for example, in a hydrogen tube from a cobalt blue to a pink. It also changes the spectrum of the strata; moreover, the spectra of the illuminated terminals and the strata differ.

6. If the discharge is irregular and the strata indistinct, an alteration of the amount of current makes the strata distinct and steady. Most frequently a point of steadiness is produced by the careful introduction of external resistance; subsequently the introduction of more resistance produces a new phase of unsteadiness, and still more resistance another phase of steady and distinct stratification.

7. The greatest heat is in the vicinity of the strata. This can be best observed when the tube contains either only one stratum, or a small number separated by a broad interval. There is reason to believe that even in the dark discharge there may be strata, for we have found a development of heat in the middle of a tube in which there was no illumination except on the terminals.

8. Even when the strata are in all appearance, perfectly steady, a pulsation can be detected in the current; but it is not proved that the strata depend upon intermittence.

9. There is no current from a battery through a tube divided by a glass division into two chambers, and the tube can only be illuminated by alternating charges.

10. In the same tube and with the same gas a very great variety of phenomena can be produced by varying the pressure and the current. The luminosities and strata, in their various forms, can be reproduced in the same tube, or in others having similar dimensions.

11. At the same pressure and with the same current the diameter of the tube affects the character of the discharge and the form and closeness of the stratification.

APPARATUS FOR MEASURING FIRE DAMP.

THE principle of this apparatus is based upon the property of palladium, when in a red hot state, of oxidizing fire-damp (carbureted hydrogen) into carbonic acid gas and water. The apparatus is constructed by Mr. Coquillon in two different shapes, namely, the *grisoumètre portatif* and *grisoumètre fixe*. Fig. 1 represents the portable grisometer. With it the quantity of fire damp contained in the air can be determined at any place in a very short time.

A represents a graduated glass cylinder, open at the bottom, but closed on top by a perforated rubber stopper. A palladium wire, F, passes through two of these perforations, and is connected with a battery by means of binding screws. A small glass tube, open below but closed on top, also passes

Fig. I.

through the stopper. The tube, A, is inclosed in a larger glass tube, B, also provided with a rubber stopper, through which another small tube like the one just described passes. A vessel, M, the bottom of which is composed of some membrane, is attached to the lower end of B. All these parts are inclosed in a sheet metal box or cylinder provided with two vertical slots for the purpose of enabling a person to read the scales. Before operating with the apparatus it is entirely filled with water. By opening the two small glass tubes and pressing the membrane upwards by the screw, S, a certain quantity of the gas or air to be examined can be admitted into the cylinders, A and B. The two small glass tubes are then closed, and the palladium is heated until it is red hot by means of the battery. As soon as the carbureted hydrogen is oxidized the levels in the two cylinders are made equal, the scales will indicate their position, and from the diminution of the water the quantity of carbureted hydrogen can be determined.

The fixed grisometer (Fig. 2) is adapted for measuring larger quantities of air. A is the graduated tube, B the palladium wire, C is a tube containing the gas or air, and F a

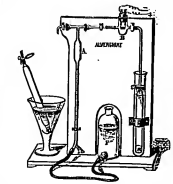

Fig. II.

vessel containing water. If the quantity of carbureted hydrogen is over 9 per cent., it will be necessary to mix the gas with air, as there always must be a surplus of oxygen. If a closed tube, D (Fig. 3), containing lye, be added to the apparatus, the same can be used for measuring any carbureted

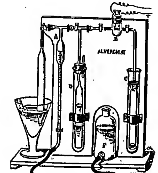

Fig. III.

gas, and is then known as the carborometer. For complicated gases it will be necessary to insert several tubes into D.—*Chemiker Zeitung.*

THE CONFINES OF MATTER.

N. Y. Sept 21/1879

In a lecture delivered in the latter part of last month before the British Association, Professor W. F. Crookes (who will, perhaps, be best remembered by the general public for his investigations of Spiritualism and his invention of the radiometer or so-called "light-mill," although its action is due not to light but to the molecular movements in the confined gas which are set up by heat) gave an extended account of his experiments in "radiant matter," or matter as far removed in its phenomena from gas as gas is removed from fluids. As long ago as 1816 Faraday suspected the existence of matter in this form, and although he did not experimentally know it, gave it the name which Professor Crookes has now adopted. In Dr. Bence Jones's "Life and Letters of Faraday" the following quotation is given: "I may now notice a curious progression in physical properties accompanying changes of form which is perhaps sufficient to induce in the inventive and sanguine philosopher a considerable degree of belief in the association of the radiant form with the others in the set of changes I have mentioned. As we ascend from the solid to the fluid and gaseous states physical properties diminish in number and variety, each state losing some of those which belonged to the preceding state. When solids are converted into fluids all the varieties of hardness and softness are necessarily lost. Crystalline and other shapes are destroyed. Opacity and color frequently give way to a colorless transparency, and a general mobility of particles is conferred. Passing onwards to the gaseous state, still more of the evident characters of bodies are annihilated. The immense differences in their weight almost disappear; the remains of difference in color that were left are lost. Transparency becomes universal, and they are all elastic. They now form but one set of substances, and the varieties of density, hardness, opacity, color, elasticity and form which render the number of solids and fluids almost infinite are now supplied by a few slight variations in weight and some unimportant shades of color. To those, therefore, who admit the radiant form of matter, no difficulty exists in the simplicity of the properties it possesses, but rather an argument in their favor. These persons show you a gradual resignation of properties in the matter we can appreciate as the matter ascends in the scale of forms, and they would be surprised if that effect were to cease at the gaseous state. They point out the greater exertions which nature makes at each step of the change, and think that, consistently, it ought to be greatest in the passage from the gaseous to the radiant form." According to this conception, radiant matter would bear no small resemblance to the "ultra-mundane corpuscles" which Le Sage imagined to be the physical cause of gravitation, coming in all directions from regions far beyond that part of the system of the world which is in any way known to us and driving bodies towards each other by physical impact. The present theory of gases is that they are composed of an almost infinite number of molecules which are constantly moving in every direction with velocities of all conceivable magnitudes. It follows from the vast number of these molecules that no molecule can move far in any direction without coming in contact with some other molecule. But if we exhaust the air or gas in a closed vessel the number of molecules is lessened, and the distance through which any one of them may pass without encountering another is increased, the length of the mean free path being inversely proportioned to the number of molecules present. The further this process is continued the longer becomes the mean free path, and the more the physical properties of the gas are modified. At a certain point of exhaustion the phenomena of the radiometer are possible, and the sails of the "mill" are turned by the radiant or straight-line motion of the molecules. When the exhaustion is carried still further, phenomena occur which are very distinct from those of air or gas at ordinary tension—so far removed, indeed, as to present matter in a state as distinct from gas as gas is from a liquid. In this fourth state "we seem at length to have within our grasp and obedient to our control the little indivisible particles which, with good warrant, are supposed to constitute the physical basis of the universe"—in other words, we have actually touched the borderland of matter and are on the threshold of the storehouse of force and energy—at the crag on which at the bidding of Force and Strength Hephaistos bound Prometheus for giving celestial fire to mankind.

When a discharge from an induction coil is passed through a vacuum tube—a perfect vacuum, it should be remembered, it is impossible to obtain—a dark space is seen around the negative pole, and this dark space increases and diminishes as the vacuum is varied according as the mean free path of the molecules increases or diminishes, being less when a greater number of molecules is present than with a smaller number. The thickness of the dark space is the measure of the mean free path between successive collisions of the molecules of the residual gas. By coming in contact with the negative pole of the coil the molecules are negatively electrified and rebound, keeping back the more slowly moving molecules which are advancing towards that pole, and the gaseous residue within the dark space is in an entirely different state from that of the residual gas in vessels at a lower degree of exhaustion. When a high state of exhaustion is reached the dark space—as Professor Crookes showed in his experiments before the British Association, his lecture being illustrated throughout with ocular demonstrations—may be widened out till it entirely fills the tube, and here by great rarefaction the mean free path becomes so long that the collisions of the molecules may be disregarded and the average molecule be considered as allowed to obey its own laws of motion without interference. They are able under the influence of the negative electricity imparted to them to dart transversely across the tube with comparatively few collisions, and radiating from the pole with enormous velocity they assume properties so novel and so characteristic as to justify their name of "radiant matter." The radiant matter darting to a head athwart the dark space excites luminosity at its borders, where its velocity is arrested by the residual gas outside of the dark space when this does not fill the tube, but when there is no residual gas the molecules will have their velocity arrested only when they reach the sides of the glass; and here we come to the first and one of the most noteworthy properties of radiant matter discharged from the negative pole—its power, namely, of exciting phosphorescence when it strikes against solid matter. The number of bodies which respond luminously to this molecular bombardment is very great, and the resulting colors are of every variety. When a diamond is thus bombarded in a dark room it shines with as much light as a candle, phosphorescing with a bright green, and rubies shine with a brilliant rich red tone, as if they were glowing hot, as also does precipitated alumina. The phosphorescent properties of radiant matter are best developed in a vacuum equal to about one one-millionth of an atmosphere, after which it diminishes till the induction spark is unable to pass. The second property of radiant matter, as developed in Professor Crookes's experiments, is that it proceeds in straight lines and absolutely refuses to turn a corner. It will be remembered that a phosphorescent light appeared where the beam of radiant matter was arrested by the side of the vacuum tube; if now a V-shaped tube be employed, a pole being at the extremity of each arm, the whole of the right arm will be flooded with light when the electricity is there turned on, which, however, stops abruptly at the bottom of the arm and will not turn the corner—the same being the case with the left arm when the conditions are reversed, the light always following the negative pole and leaving the positive side with scarcely any luminosity. This is entirely at variance with the phenomena ordinarily exhibited in vacuum tubes which are not highly enough exhausted to exhibit the properties of the fourth form of matter. In such tubes the luminosity caused by the phosphorescence of residual gas follows all the convolutions into which glass-blowers can contrive to twist the glass. The negative pole being at one end and the positive pole at the other in such cases, the luminous phenomena seem to depend more on the positive than on the negative, but at a very high exhaustion the phenomena noticed in the ordinary vacuum tube when the induction spark passes through it—an appearance of cloudy luminosity and of stratifications—wholly disappear. No cloud or fog whatever is seen in the body of the tube, and the only light observed is that from the phosphorescent surface of the glass. Moreover, in a low vacuum the position of the positive pole is of every importance, while in a high vacuum its position scarcely matters at all, the phenomena seeming to depend entirely on the negative pole. If the negative pole points in the direction of the positive, all very well, but if it is entirely in the opposite direction it is of little consequence—the radiant matter darts all the same in a straight line from the negative. Another property of this newly discovered form of matter is that when it is intercepted by solid matter it casts a shadow. Radiant matter comes from the pole in straight lines, and does not merely permeate all parts of the tube and fill it with light, as would be the case were the exhaustion less good. Where there is nothing in the way the rays strike the glass and produce phosphorescence, and where solid matter intervenes they are obstructed and a shadow is cast. If a cruciform screen of aluminium is introduced into the tube so as to intercept some of the molecules darting from the negative pole a shadow will be cast on the glass behind the screen, and where the molecules have shot past the edges of the aluminium and fallen on the tube the glass where they have made their impact will presently become so hammered and bombarded as to have grown "tired"—that is, its sensibility will be lessened so that it will fail to respond easily to additional excitement. But the part on which the shadow of the cross has fallen is not tired, but perfectly fresh, and when the screen is made to drop, the shadow will at once shine brilliantly inside of the tired and somewhat darkened area of the former phosphorescence. Glass thus bombarded never recovers its first sensibility, and this demonstrates another property of radiant matter, which is that it is projected with great velocity from the negative pole and not only strikes the glass in such a way as to cause it to vibrate and become temporarily luminous while the discharge is going on, but the molecules hammer away with sufficient energy to produce a permanent impression on the glass. Moreover, radiant matter exerts strong mechanical action where it strikes. It has just been shown that it is arrested by solid matter placed in its path. If this solid matter is easily moved the impact of the molecules will reveal itself in mechanical action. A

small wheel so placed that the molecules may play upon its paddles will revolve as in the radiometer, the swiftness of its revolutions increasing with the increase of the exhaustion of the tube, and if a ring of platinum wire in the tube be made hot with the aid of a galvanic battery the intensity of the motion of the wheel will be still further increased, showing that in a high vacuum radiant matter is excited not only by the negative pole of an induction coil, but also by heat directly applied. Still another and in some respects a most curious property of this form is that matter in this state of tenuity is deflected by a magnet. A tube is taken having at one end a small potash tube which if heated will slightly lower the vacuum. When the induction coil is turned on and a magnet is placed under the tube a ray of radiant matter traces its trajectory along the tube in a curved line under the influence of the magnet. These molecules, it should be remembered, are true projectiles shot from the negative pole, and may be likened to a discharge of iron bullets from a mitrailleuse, while the magnet beneath will represent the earth curving the trajectory of the shot by gravitation. Here, as in all projectiles, if the deflecting force remains constant, the curve traced by the projectile varies with the velocity. The velocity of the molecules cannot here be directly varied, but their velocity may be impeded by lowering the vacuum, by admitting more molecules to the tube, which is accomplished by vaporizing part of the potash. Instantly the stream of projected radiant matter responds, the magnetism has a longer time to act on each of the molecules, the trajectory becomes more and more curved with the increasing vaporization of the potash, until, instead of shooting nearly to the end of the tube, the molecular bullets fall to the bottom before they have got half way. In the case of the wheel mentioned above, the stream can be so deflected by aid of the magnet that the wheel may be driven either as an over-shot or under-shot water-wheel. Radiant matter also produces heat when its motion is arrested. If a small tube be taken with a cup-shaped negative pole, the molecules may be projected to a focus in the middle of the tube, whence by a magnet they may be deflected to the side and made to fall upon a bit of wax, which will presently melt. But so intense becomes the heat under the hammering of the molecules, as a blacksmith beats his iron to redness on his anvil, that soon the glass itself softens, the atmosphere presses it in and it melts completely. Iridio-platinum is one of the most refractory of metals—one with which Mr. Edison has of late been experimenting for use in his electric lamp—but it yields to the power of the radiant molecules, which, being centred upon it, first raise it to a white heat, then cause it to glow with almost insupportable brilliancy and then melt it like lead. Touching the chemistry of radiant matter, Professor Crookes has experimented with many varieties of matter reduced to the radiant state, and finds that whether the gas be hydrogen, carbonic acid or atmospheric air, the molecules retain their chemical characteristics. By introducing into the tubes appropriate absorbents of residual gas it is seen that chemical attraction goes on long after the attenuation has reached its best stage for the exhibition of physical phenomena, and this even when the degree of tenuity has reached the one twenty-millionth of an atmosphere, a degree which corresponds to about the one hundredth of an inch in a barometric column three miles high. So far, therefore, as it can at present be said, the radiant form of matter differs from the three other forms solely in its physical characters, as only indeed it might have been expected to differ, chemical changes being molecular and molecules being the "manufactured article," of which the material universe is composed. The formation of a molecule is an event which does not belong to the present system of nature; so far as we know, it is not going on on the earth or in the sun or in the stars, nor has it so gone on since these bodies began to be formed, and as all matter, in whatever form, is composed of molecules, it was to be expected that, when acting in a free path they would still retain their intimate chemical relations when by chance they should be brought in contact with other and different molecules.

In the exhaustion of his tubes Professor Crookes brought matter to such an extreme of tenuity that it is objected to his work that primary importance can hardly be attached to it. But when all is said, a tube containing a gas at a density of one one-millionth of an atmosphere is far from holding a vacuum. In one of his experiments he used a bulb about five and two-fifths in diameter. According to the best authorities such a bulb contains more than 1,000,000,000,000,000,000—a million million million molecules. When exhausted to a one-millionth of an atmosphere it would still retain a million million molecules, of which 800,000,000 placed in a row would cover about a linear inch, and such a number of molecules certainly justifies the treatment of them as matter. The mind has no picture of such a number, but to suggest some idea of it, the Professor perforated his exhausted bulb with a spark from the induction coil, producing a hole of microscopic fineness which was, nevertheless and of course sufficiently large to allow molecules to enter and destroy the vacuum. Supposing that the bulb were indestructible and had been pierced at the time of the birth of the solar system, supposing it to have been present when the earth was without form and void, supposing it to have borne witness to all the stupendous changes evolved during the full cycles of geologic time, "to have seen the first living creature appear and the last man to disappear, supposing it to survive until the fulfilment of the mathematician's prediction that the sun, the source of energy, four million centuries from its formation will ultimately become a burnt-out cinder," supposing that molecules entered the bulb continuously at the rate of one hundred million a second, the bulb would hardly then have admitted its full quadrillion of molecules. As matter of fact it took but about ten minutes to fill the vacuum through the hole thus punctured, so that, instead of entering through the microscopic puncture at the rate of 100,000,000 a second, the rate must have been something like three hundred trillions per second. It is in the bombardment of particles of such exceeding smallness as this that the reduction of the most refractory substances is due when the molecules act as radiant matter. In some of its properties, as the experiments of Professor Crookes show, the properties of this form of matter show it to be as material as a stone, while in others it assumes almost the character of radiant energy, and when dealing with it we seem to be in the shadowy realm between the known and the unknown, on the very boundaries of the "Unseen Universe," where force and matter meet in their most intimate occult relations.

MR. CROOKES ON RADIANT MATTER.

Eng Mechanic Sept 5 1879

DURING the meeting of the British Association, Mr. W. Crookes delivered the Friday evening lecture in the Albert Hall, Sheffield, on a subject he has made peculiarly his own, viz., Radiant Matter. The title of the lecture, and the name of the phenomena it described, is borrowed from one of Faraday's lectures, in which that great philosopher said:—"If we conceive a change as far beyond vaporisation as that is above fluidity, and then take into account also the proportional increased extent of alteration as the changes rise, we shall perhaps, if we can form any conception at all, not fall far short of Radiant Matter; and as in the last conversion many qualities were lost, so here also many more would disappear." About three years afterwards (1819) Faraday, while admitting that the existence of radiant matter had not been proved, demonstrated the probability of its existence. It was left to Mr. Crookes, *facile princeps* in the art of experimentation, to prove that there is such a state of matter, and on December 5, last year, he described his researches, and exhibited their results before the Royal Society (see p. 383, Vol. XXVIII.). Since then he has made numerous further experiments and has constructed many elaborate and expensive pieces of apparatus, some of which were used in the lecture, which, we need scarcely say, was attended by a distinguished if not numerous audience. Readers of the article above mentioned and of Mr. Crookes's paper, p. 572 ante, will be familiar with the principal phenomena of an ultra-gaseous state of matter, and of the "dark space" rendered visible in a vacuum tube. This dark space is found to increase and diminish as the vacuum is varied, and is found to be the mean free path of the molecules of the residual gas. Mr. Crookes exhibited a great variety of apparatus and made many experiments, fully convincing his audience of the truth of Faraday's expression, radiant matter. The first experiment was the now familiar demonstration that radiant matter exerts powerful phosphorogenic action where it strikes, and the variety of phosphorescence was shown by means of bulbs of uranium glass, phosphorescing green, English glass, blue, and a soft German glass which phosphoresces a bright apple green. Many other substances possess the phosphorescent power in a higher degree than glass—notably the luminous sulphide of calcium,—but the diamond is the most sensitive that Mr. Crookes has yet met with. A curious fluorescent diamond, green by daylight and colourless by candlelight, was mounted in an exhausted bulb, and the molecular discharge was directed upon it from below upwards, when, the room being darkened, the diamond shone with as much light as a candle, phosphorescing of a bright green. Mr. Crookes then exhibited a tube containing a fine collection of ruby pebbles, which, as soon as the induction-spark was turned on, shone with a brilliant rich red tone, as if glowing hot, although some of the stones were so pale as to be almost colourless. The ruby is nothing more than crystallised alumina with a little colouring matter, but its rich red phosphorescence is a property of the alumina, for Mr. Crookes showed that some precipitated alumina glowed under the molecular discharge with the same rich red colour. There is one particular degree of exhaustion more favourable than any other for the development of the properties of radiant matter. Roughly speaking, it may be put at the millionth of an atmosphere. At this degree of exhaustion the phosphorescence is very strong, and after that it begins to diminish until the spark refuses to pass. This fact Mr. Crookes demonstrated by means of a vacuum tube in which the exhaustion had been carried as far as possible, and to which a smaller tube containing some fragments of caustic potash was attached. By heating the latter a trace of aqueous vapour was sent into the larger tube, and the degree of exhaustion being thus reduced the phenomena of phosphorescence made their appearance in the otherwise non-conducting tube.

Mr. Crookes then showed that the radiant matter whose impact on the glass causes an evolution of light, absolutely refuses to turn a corner. It would illuminate one arm of a V-shaped tube, but would not enter the other. In the ordinary phenomena exhibited by vacuum tubes it is customary, in order to bring out the striking contrasts of colour, to bend the tubes into very elaborate designs. The luminosity, caused by the phosphorescence of the residual gas follows all the convolutions into which skilful glass-blowers can manage to twist the glass. The negative pole being at one end and the positive pole at the other, the luminous phenomena seem to depend more on the positive than on the negative at the ordinary exhaustion hitherto used to get the best phenomena of vacuum tubes. But at a very high exhaustion the phenomena noticed in ordinary vacuum tubes when the induction spark passes through them—an appearance of cloudy luminosity and of stratifications—disappear entirely. In the low vacuum the position of the positive pole is of every importance, whilst in a high vacuum the position of the positive pole scarcely matters at all; the phenomena seem to depend entirely on the negative pole. If the negative pole points in the direction of the positive, all very well, but if the negative pole is entirely in the opposite direction it is of little consequence: the radiant matter darts all the same in a straight line from the negative. Radiant matter comes from the pole in straight lines, and does not merely permeate all parts of the tube and fill it with light, as would be the case were the exhaustion less good. Where there is nothing in the way the rays strike the screen and produce phosphorescence, and where solid matter intervenes they are obstructed by it, and a shadow is thrown on the screen. This was shown by means of a tube containing a cross of aluminium, which partly intercepted the rays from the negative pole, and the shadow of which was thrown upon the luminous end of the tube. By an ingenious arrangement the cross is made to fall down out of the way, when, instead of the black shadow, a luminous cross is seen, because the background is capable of only faintly phosphorescing, whilst the part which had the black shadow upon it retains its full phosphorescent power. Here, therefore, is another important property of radiant matter. It is projected with great velocity from the negative pole, and not only strikes the glass in such a way as to cause it to vibrate and become temporarily luminous while the discharge is going on, but the molecules hammer away with sufficient energy to produce a permanent impression upon the glass.

Mr. Crookes then showed by means of a little paddle-wheel mounted on rails within a tube, that radiant matter exerts strong mechanical action where it strikes, for the little wheel was made to run backwards and forwards by reversing the stream of radiant matter. This experiment was repeated in other forms, and it was shown that radiant matter in high vacua is not only excited by the negative pole of an induction coil, but that a hot wire will set it in motion with sufficient force to drive a radiometer vane-wheel. Experiments were also made to show the effect of a magnet upon the line of phosphorescent light, and to prove that radiant matter is deflected by magnetic action. This was effectively shown upon the screen by means of a little wheel which was made to turn in alternate directions by the deflection of the radiant matter against its upper or lower paddles. Radiant matter also produces heat when its motion is arrested. The glass becomes very warm where the green phosphorescence is strongest. Mr. Crookes demonstrated this fact by showing that the focus became so hot that glass was melted, while in another experiment he caused a piece of iridio-platinum to become white hot, to glow with almost insupportable brilliancy, and

102

finally to melt. Mr. Crookes stated that the highest vacuum he has yet succeeded in obtaining was the 1-20,000,000th of an atmosphere, a degree which corresponds to about the hundredth of an inch in a barometrical column three miles high. In conclusion the lecturer said that "We have actually touched the border land where matter and energy seem to merge into one another, the shadowy realm between known and unknown, which for me has always had peculiar temptations. I venture to think that the greatest scientific problems of the future will find their solution in this border land, and even beyond; here, it seems to me, lie ultimate realities, subtle, far-reaching, wonderful."

103

ON RADIANT MATTER[1]

TO throw light on the title of this lecture I must go back more than sixty years—to 1816. Faraday, then a mere student and ardent experimentalist, was twenty-four years old, and at this early period of his career he delivered a series of lectures on the general properties of matter, and one of them bore the remarkable title, "On Radiant Matter." The great philosopher's notes of this lecture are to be found in Dr. Bence Jones's "Life and Letters of Faraday," and I will here quote a passage in which he first employs the expression *Radiant Matter*:—

"If we conceive a change as far beyond vaporisation as that is above fluidity, and then take into account also the proportional increased extent of alteration as the changes rise, we shall perhaps, if we can form any conception at all, not fall far short of radiant matter; and as in the last conversion many qualities were lost, so here also many more would disappear."

Faraday was evidently engrossed with this far-reaching speculation, for three years later—in 1819—we find him bringing fresh evidence and argument to strengthen his startling hypothesis. His notes are now more extended, and they show that in the intervening three years he had thought much and deeply on this higher form of matter. He first points out that matter may be classed into four states—solid, liquid, gaseous, and radiant—these modifications depending upon differences in their several essential properties. He admits that the existence of radiant matter is as yet unproved, and then proceeds, in a series of ingenious analogical arguments, to show the probability of its existence.[2]

If, in the beginning of this century, we had asked, What is a gas? the answer then would have been that it is matter, expanded and rarefied to such an extent as to be impalpable, save when set in violent motion; invisible, incapable of assuming or of being reduced into any definite form like solids, or of forming drops like liquids; always ready to expand where no resistance is offered, and to contract on being subjected to pressure. Sixty years ago such were the chief attributes assigned to gases. Modern research, however, has greatly enlarged and modified our views on the constitution of these elastic fluids. Gases are now considered to be composed of an almost infinite number of small particles or molecules, which are constantly moving in every direction with velocities of all conceivable magnitudes. As these molecules are exceedingly numerous, it follows that no molecule can move far in any direction without coming in contact with some other molecule. But if we exhaust the air or gas contained in a closed vessel, the number of molecules becomes diminished, and the distance through which any one of them can move without coming in contact with another is increased, the length of the mean free path being inversely proportional to the number of molecules present. The further this process is carried the longer becomes the average distance a molecule can travel before entering into collision; or, in other words, the longer its mean free path the more the physical properties of the gas or air are modified. Thus, at a certain point, the phenomena of the radiometer become possible, and on pushing the rarefaction still further, *i.e.*, decreasing the number of molecules in a given space and lengthening their mean free path, the experimental results are obtainable to which I am now about to call your attention. So distinct are these phenomena from anything which occurs in air or gas at the ordinary tension, that we are led to assume that we are here brought face to face with matter in a fourth state or condition, a condition as far removed from the state of gas as a gas is from a liquid.

Mean Free Path. Radiant Matter

I have long believed that a well-known appearance observed in vacuum tubes is closely related to the phenomena of the mean free path of the molecules. When the negative pole is examined while the discharge from an induction-coil is passing through an exhausted tube, a dark space is seen to surround it. This dark space is found to increase and diminish as the vacuum is varied, in the same way that the mean free path of the molecules lengthens and contracts. As the one is perceived by the mind's eye to get greater, so the other is seen by the bodily eye to increase in size; and if the vacuum is insufficient to permit much play of the molecules before they enter into collision, the passage of electricity shows that the "dark space" has shrunk to small dimensions. We naturally infer that the dark space is the mean free path of the molecules of the residual gas, an inference confirmed by experiment.

I will endeavour to render this "dark space" visible to all present. Here is a tube (Fig. 1) having a pole in the centre in

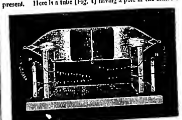

FIG. 1.

the form of a metal disk, and other poles at each end. The centre pole is made negative, and the two end poles connected together are made the positive terminal. The dark space will be in the centre. When the exhaustion is not very great the dark space extends only a little on each side of the negative pole in the centre. When the exhaustion is good, as in the tube before you, and I turn on the coil, the dark space is seen to extend for about an inch on each side of the pole.

Here, then, we see the induction spark actually illuminating the lines of molecular pressure caused by the excitement of the negative pole. The thickness of this dark space is the measure of the mean free path between successive collisions of the molecules of the residual gas. The extra velocity with which the negatively electrified molecules rebound from the excited pole, keeps back the more slowly moving molecules which are advancing towards that pole. A conflict occurs at the boundary of the dark space, where the luminous margin bears witness to the energy of the discharge.

Therefore the residual gas—or, as I prefer to call it, the gaseous residue—within the dark space, is in an entirely different state to that of the residual gas in vessels at a lower degree of exhaustion. To quote the words of our last year's President, in his address at Dublin:—

"In the exhausted column we have a vehicle for electricity not constant like an ordinary conductor, but itself modified by the passage of the discharge, and perhaps subject to laws differing materially from those which it obeys at atmospheric pressure."

In the vessels with the lower degree of exhaustion, the length of the mean free path of the molecules is exceedingly small as compared with the dimensions of the bulb, and the properties belonging to the ordinary gaseous state of matter, depending upon constant collisions, can be observed. But in the phenomena now about to be examined, so high is the exhaustion carried that the dark space around the negative pole has widened out till it entirely fills the tube. By great rarefaction the mean free path

[1] A lecture delivered to the British Association for the Advancement of Science, at Sheffield, Friday, August 22, 1879, by William Crookes, F.R.S.

[2] "I may now notice a curious progression in physical properties accompanying changes of form, and which is perhaps sufficient to induce, in the inventive and sanguine philosopher, a considerable degree of belief in the association of the radiant form with the others in the set of changes I have mentioned.

"As we ascend from the solid to the fluid and gaseous states, physical properties diminish in number and variety, each state losing some of those which belonged to the preceding state. When solids are converted into fluids, all the varieties of hardness and softness are necessarily lost. Crystalline and other shapes are destroyed. Opacity and colour frequently give way to a colourless transparency, and a general mobility of particles is conferred.

"Passing onward to the gaseous state, still more of the evident characters of bodies are annihilated. The immense differences in their weight almost disappear; the remains of difference in colour that were left are lost. Transparency becomes universal, and they are all elastic. They now form but one set of substances, and the varieties of density, hardness, opacity, colour, elasticity, and form, which render the number of solids and fluids almost infinite, are now supplied by a few slight variations in weight, and some unimportant shades of colour.

"To those, therefore, who admit the radiant form of matter, no difficulty exists in the simplicity of the properties it possesses, but rather an argument in their favour. These persons show you a gradual resignation of properties in the matter we can appreciate as the matter ascends in the scale of forms, and they would be surprised if that effect were to cease at the gaseous state. They point out the greater exertions which nature makes at each step of the change, and think that, consistently, it ought to be greatest in the passage from the gaseous to the radiant form."—*Life and Letters of Faraday*, vol. i. p. 308.

(*Phrynosoma cornutum*) from Texas, presented by Mr. Ernest E. Sabel; a Sulphur-breasted Toucan (*Ramphastos carinatus*), three Black-necked Stilt Plovers (*Himantopus nigricollis*), two Cayenne Lapwings (*Vanellus cayennensis*) from South America, a Slow Loris (*Nycticebus tardigradus*) from Malacca, a Radiated Tortoise (*Testudo radiata*) from Madagascar, two Electric Silurus (*Malapterurus beninensis*) from West Africa, purchased; a Squirrel-like Phalanger (*Belideus sciureus*), born in the Gardens.

ON RADIANT MATTER[1]

Nature Sept 4 '79

Radiant Matter exerts strong Mechanical Action where it Strikes

WE have seen, from the sharpness of the molecular shadows, that radiant matter is arrested by solid matter placed in its path.

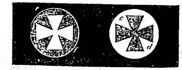

FIG. 10.

If this solid body is easily moved the impact of the molecules will reveal itself in strong mechanical action. Mr. Gimingham has constructed for me an ingenious piece of apparatus which when placed in the electric lantern will render this mechanical action visible to all present. It consists of a highly-exhausted glass tube (Fig. 11), having a little glass railway running along it from one end to the other. The axle of a small wheel revolves on the rails, the spokes of the wheel carrying wide mica paddles. At each end of the tube, and rather above the centre, is an aluminium pole, so that whichever pole is made negative the stream of radiant matter darts from it along the tube, and striking the upper vanes of the little paddle-wheel, causes it to turn round and travel along the railway. By reversing the poles I can arrest the wheel and send it the reverse way, and if I gently incline the tube the force of impact is observed to be sufficient even to drive the wheel up-hill.

This experiment therefore shows that the molecular stream

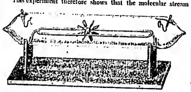

FIG. 11.

from the negative pole is able to move any light object in front of it.

The molecules being driven violently from the pole there should be a recoil of the pole from the molecules, and by arranging an apparatus so as to have the negative pole movable and the body receiving the impact of the radiant matter fixed, this recoil can be rendered sensible. In appearance the apparatus (Fig. 12) is not unlike an ordinary radiometer with aluminium disks for vanes, each disk coated on one side with a film of mica. The fly is supported by a hard steel instead of glass cup, and the needle point on which it works is connected by means of a wire with a platinum terminal sealed into the glass. At the top of the radiometer bulb a second terminal is sealed in. The radiometer therefore can be connected with an induction-coil, the movable fly being made the negative pole.

For these mechanical effects the exhaustion need not be so high as when phosphorescence is produced. The best pressure for this electrical radiometer is a little beyond that at which the dark space round the negative pole extends to the sides of the glass bulb. When the pressure is only a few millims. of mercury, on passing the induction current a halo of velvety violet light forms on the metallic side of the vanes, the mica side remaining dark. As the pressure diminishes, a dark space is seen to separate the violet halo from the metal. At a pressure of half a millim. this dark space extends to the glass, and rotation commences. On continuing the exhaustion the dark space further widens out and appears to flatten itself against the glass, when the rotation becomes very rapid.

Here is another piece of apparatus (Fig. 13) which illustrates

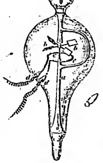

FIG. 12.

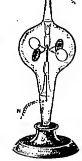

FIG. 13.

the mechanical force of the radiant matter from the negative pole. A stem (*a*) carries a needle-point in which revolves a light mica fly (*b b*). The fly consists of four square vanes of thin clear mica, supported on light aluminium arms, and in the centre is a small glass cap which rests on the needle-point. The vanes are inclined at an angle of 45° to the horizontal plane. Below the fly is a ring of fine platinum wire (*c c*), the ends of which pass through the glass at *d d*. An aluminium terminal (*e*) is sealed in at the top of the tube, and the whole is exhausted to a very high point.

By means of the electric lantern I project an image of the vanes on the screen. Wires from the induction-coil are attached,

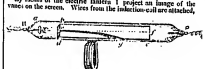

FIG. 14.

so that the platinum ring is made the negative pole, the aluminium wire (*e*) being positive. Instantly, owing to the projection of radiant matter from the platinum ring, the vanes rotate with extreme velocity. Thus far the apparatus has shown nothing more than the previous experiments have prepared us to expect; but observe what now happens. I disconnect the induction-coil altogether, and connect the two ends of the platinum wire with a small galvanic battery; this makes the ring *c c* red-hot, and under this influence you see that the vanes spin as fast as they did when the induction-coil was at work.

Here, then, is another most important fact. Radiant matter in these high vacua is not only excited by the negative pole of an induction-coil, but a hot wire will set it in motion with force sufficient to drive round the sloping vanes.

[1] A lecture delivered to the British Association for the Advancement of Science, at Sheffield, Friday, August 22, 1879, by William Crookes, F.R.S. Continued from p. 423.

Radiant Matter is deflected by a Magnet

I now pass to another property of radiant matter. This long glass tube (Fig. 14), is very highly exhausted; it has a negative pole at one end (*a*) and a long phosphorescent screen (*b*, *c*) down the centre of the tube. In front of the negative pole is a plate of mica (*b*, *d*) with a hole (*e*) in it, and the result is, when I turn on the current, a line of phosphorescent light (*e*, *f*) is projected along the whole length of the tube. I now place beneath the tube a powerful horse-shoe magnet: observe how the line of light (*e*, *g*) becomes curved under the magnetic influence waving about like a flexible wand as I move the magnet to and fro.

This action of the magnet is very curious, and if carefully followed up will elucidate other properties of radiant matter. Here (Fig. 15) is an exactly similar tube, but having at one end a small potash tube, which if heated will slightly injure the vacuum. I turn on the induction current, and you see the ray of radiant matter tracing its trajectory in a curved line along the screen, under the influence of the horse-shoe magnet beneath. Observe the shape of the curve. The molecules shot from the negative pole may be likened to a discharge of iron bullets from a mitrailleuse, and the magnet beneath will represent the earth curving the trajectory of the shot by gravitation. Here on this luminous screen you see the curved trajectory of the shot accurately traced. Now suppose the deflecting force to remain constant, the curve traced by the projectile varies with the velocity. If I put more powder in the gun the velocity will be greater and the trajectory flatter, and if I interpose a denser resisting medium between the gun and the target, I diminish the velocity of the shot, and thereby cause it to move in a greater curve and come to the ground sooner. I cannot well increase before you the velocity of my stream of radiant molecules by putting more

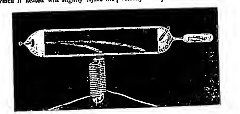

FIG. 15.

powder in my battery, but I will try and make them suffer greater resistance in their flight from one end of the tube to the other. I heat the caustic potash with a spirit-lamp and so throw in a trace more gas. Instantly the stream of radiant matter responds. Its velocity is impeded, the magnetism has longer time on which to act on the individual molecules, the trajectory gets more and more curved, until, instead of shooting nearly to the end of the tube, my molecular bullets fall to the bottom before they have got more than half-way.

It is of great interest to ascertain whether the law governing the magnetic deflection of the trajectory of radiant matter is the same as has been found to hold good at a lower vacuum. The experiments I have just shown you were with a very high vacuum. Here is a tube with a low vacuum (Fig. 16). When I turn on the induction spark, it passes as a narrow line of violet light

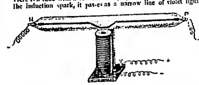

FIG. 16.

joining the two poles. Underneath I have a powerful electro-magnet. I make contact with the magnet, and the line of light dips in the centre towards the magnet. I reverse the poles, and the line is driven up to the top of the tube. Notice the difference between the two phenomena. Here the action is temporary. The dip takes place under the magnetic influence; the line of discharge then rises and pursues its path to the positive pole. In the high exhaustion, however, after the stream of radiant matter had dipped to the magnet, it did not recover itself, but continued its path in the altered direction.

By means of this little wheel, skilfully constructed by Mr. Gimingham, I am able to show the magnetic deflection in the electric lantern. The apparatus is shown in this diagram (Fig. 17). The negative pole (*a*, *b*) is in the form of a very shallow cup. In front of the cup is a mica screen (*c*, *d*), wide enough to intercept the radiant matter coming from the negative pole. Behind this screen is a mica wheel (*e*, *f*) with a series of vanes, making a sort of paddle-wheel. So arranged, the molecular rays from the pole *a b* will be cut off from the wheel, and will not produce any movement. I now put a magnet, *g*, over the tube, so as to deflect the stream over or under the obstacle *c*, *d*, and the result will be rapid motion in one or the other direction, according to the way the magnet is turned. I throw the image of the apparatus on the screen. The spiral lines painted on the wheel show which way it turns. I arrange the magnet to draw the molecular stream so as to beat against the upper vanes, and the wheel revolves rapidly as if it were an over-shot water-wheel. I turn the magnet so as to drive the radiant

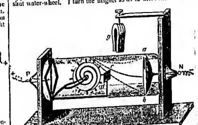

FIG. 17.

matter underneath; the wheel slackens speed, stops, and then begins to rotate the other way, like an under-shot water-wheel. This can be repeated as often as I reverse the position of the magnet.

I have mentioned that the molecules of the radiant matter discharged from the negative pole are negatively electrified. It is probable that their velocity is owing to the mutual repulsion between the similarly electrified pole and the molecules. In less high vacua, such as you saw a few minutes ago (Fig. 16), the discharge passes from one pole to another, carrying an electric current, as if it were a flexible wire. Now it is of great interest

106

rays is projected along the tube. I turn the magnetism on, and draw the focus to the side of the glass. The first thing you see is a small circular patch melted in the coating of wax. The glass soon begins to disintegrate, and cracks are shooting starwise from the centre of heat. The glass is softening. Now the atmospheric pressure forces it in, and now it melts. A hole (*e*) is perforated in the middle, the air rushes in, and the experiment is at an end.

I can render this focal heat more evident if I allow it to play on a piece of metal. The bulb (Fig. 21) is furnished with a negative pole in the form of a cup (*a*). The rays will therefore be projected to a focus on a piece of iridio-platinum (*b*) supported in the centre of the bulb.

I first turn on the induction-coil slightly, so as not to bring out its full power. The focus is now playing on the metal, raising it to a white heat. I bring a small magnet near, and you see I can deflect the focus of heat just as I did the luminous focus in the other tube. By shifting the magnet I can drive the focus up and down, or draw it completely away from the metal, and leave it non-luminous. I withdraw the magnet, and let the molecules have full play again; the metal is now white hot. I increase

FIG. 21.

the intensity of the spark. The iridio-platinum glows with almost insupportable brilliancy, and at last melts.

The Chemistry of Radiant Matter

As might be expected, the chemical distinctions between one kind of radiant matter and another at these high exhaustions are difficult to recognise. The physical properties I have been elucidating seem to be common to all matter at this low density. Whether the gas originally under experiment be hydrogen, carbonic acid, or atmospheric air, the phenomena of phosphorescence, shadows, magnetic deflection, &c., are identical, only they commence at different pressures. Other facts, however, show that at this low density the molecules retain their chemical characteristics. Thus by introducing into the tubes appropriate absorbents of residual gas, I can see that chemical attraction goes on long after the attenuation has reached the best stage for showing the phenomena now under illustration, and I am able by this means to carry the exhaustion to much higher degrees than I can get by mere pumping. Working with aqueous vapour I can use phosphoric anhydride as an absorbent; with carbonic acid, potash; with hydrogen, palladium; and with oxygen, carbon, and then potash. The highest vacuum I have yet succeeded in obtaining has been the 1-20,000,000th of an atmosphere, a degree which may be better understood if I say that it corresponds to about the hundredth of an inch to a barometric column three miles high.

It may be objected that it is hardly consistent to attach primary importance to the presence of *Matter*, when I have taken extraordinary pains to remove as much matter as possible from these bulbs and these tubes, and have succeeded so far as to leave only about the one-millionth of an atmosphere in them. At its ordinary pressure the atmosphere is not very dense, and its recognition as a constituent of the world of matter is quite a modern notion. It would seem that when divided by a million, so little matter will necessarily be left that we may justifiably neglect the trifling residue and apply the term *vacuum* to space from which the air has been so nearly removed. To do so, however, would be a great error, attributable to our limited faculties being unable to grasp high numbers. It is generally taken for granted that when a number is divided by a million the quotient must necessarily be small, whereas it may happen that the original number is so large that its division by a million seems to make little impression on it. According to the best authorities, a bulb of the size of the one before you (13·5 centimetres in diameter) contains more than 1,000,000,000,000,000,000,000 (a quadrillion) molecules. Now, when exhausted to a millionth of an atmosphere we shall still have a trillion molecules left in the bulb—a number quite sufficient to justify me in speaking of the residue as *matter*.

To suggest some idea of this vast number I take the exhausted bulb, and perforate it by a spark from the induction coil. The spark produces a hole of microscopical fineness, yet sufficient to allow molecules to penetrate and to destroy the vacuum. The inrush of air impinges against the vanes, and sets them rotating after the manner of a windmill. Let us suppose the molecules to be of such a size that at every second of time a hundred millions could enter. How long, think you, would it take for this small vessel to get full of air? An hour? A day? A year? A century? Nay, almost an eternity! A time so enormous that imagination itself cannot grasp the reality. Supposing this exhausted glass bulb, indued with indestructibility, had been pierced at the birth of the solar system; supposing it to have been present when the earth was without form and void; supposing it to have borne witness to all the stupendous changes evolved during the full cycles of geologic time, to have seen the first living creature appear, and the last man disappear; supposing it to survive until the fulfilment of the mathematician's prediction that the sun, the source of energy, four million centuries from its formation, will ultimately become a burnt-out cinder;[1] supposing all this—at the rate of filling I have just described, 100 million molecules a second—this little bulb even then would scarcely have admitted its full quadrillion of molecules.[2]

But what will you say if I tell you that all these molecules, this quadrillion of molecules, will enter through the microscopic hole before you leave this room? The hole being unaltered in size, the number of molecules undiminished, this apparent paradox can only be explained by again supposing the size of the molecules to be diminished almost infinitely—so that instead of entering at the rate of 100 millions every second, they troop in at a rate of something like 300 trillions a second. I have done the sum, but figures when they mount so high cease to have any meaning, and such calculations are as futile as trying to count the drops in the ocean.

In studying this fourth state of matter we seem at length to have within our grasp and obedient to our control the little indivisible particles which with good warrant are supposed to constitute the physical basis of the universe. We have seen that in some of its properties radiant matter is as material as this table, whilst in other properties it almost assumes the character of radiant energy. We have actually touched the borderland where matter and force seem to merge into one another, the shadowy realm between Known and Unknown which for me has always

[1] The possible duration of the sun from formation to extinction has been variously estimated by different authorities, at from 18 million years to 400 million years. For the purpose of this illustration I have taken the highest estimate.

[2] According to Mr. Johnstone Stoney (*Phil. Mag.*, vol. 36, p. 141), 1 c.c. of air contains about 1,000,000,000,000,000,000,000 molecules. Therefore a bulb 13·5 centims. diameter contains $13 \cdot 5^3 \times 0 \cdot 5236 \times$ 1,000,000,000,000,000,000,000 or 1,288,252,350,000,000,000,000,000 molecules of air at the ordinary pressure. Therefore the bulb when exhausted to the millionth of an atmosphere, contains 1,288,252,350,000,000,000 molecules, leaving 1,288,251,061,747,650,000,000,000 molecules to enter through the perforation. At the rate of 100,000,000 molecules a second, the time required for them all to enter will be

12,882,510,617,476,500 seconds, or
214,708,510,291,275 minutes, or
3,578,475,171,521 hours, or
149,103,132,147 days, or
408,501,731 years.

107

CONTRIBUTIONS TO MOLECULAR PHYSICS IN HIGH VACUA[1]

II.

IT has been shown that the stream of molecules are shot off from the negative pole in a negatively charged condition, and their velocity is owing to the mutual repulsion between the similarly electrified pole and molecules. It became of interest to ascertain whether lateral repulsion was exerted between the molecules themselves. If the stream of molecules coming from the negative pole carried an electric current, two parallel rays should exert mutual attraction; but if nothing of the nature of an electric current was carried by the stream, it was likely that the two parallel rays would act simply as negatively electrified bodies and exert lateral repulsion. This was not difficult to put to the test of experiment.

A tube was made with two flat aluminium terminals, *a b*, close together at one end, and one terminal, *c*, at the other, as shown in Fig. 11. Along the centre of the tube, cutting the axis obliquely, is a screen of mica, painted over with a phosphorescent powder, and between the screen and the double poles, *a b*, is a disk of mica crossing the axis of the tube, and therefore nearly at right angles to the phosphorescent screen. In this mica disk are two slits—one opposite each pole *a* and *b*—running in such a direction that the molecular streams emanating from *a* and *b* when made negative shall pass through the slits, forming two horizontal sheets. These sheets striking against the oblique screen will be made evident as two horizontal lines of light. The poles *a* and *b* were somewhat bent, so that the lines of light were not quite parallel, but slightly converged. The tube being properly exhausted, the pole *a* was made negative, and *c* positive, the lower pole *b* being left idle. A sharp ray of phosphorescent light shot across the screen along the line *df*. The negative wire was now transferred from *a* to *b*, when a ray of light shot along the screen from *e* to *f*. The two poles *a* and *b* were now connected by a wire, and the two together were made the negative pole. Two lines of light now shone on the screen, but their positions, instead of being, as before, *df* and *ef*, were now *dg* and *eh*, as shown by the dotted lines. The wire joining the poles *a b* was removed, and the pole *a* made negative; the ray from it followed the line *df* as before. While the coil was working, another wire hanging loose from the pole *b* was brought up to *a*, so as to make them both negative. Instantly the ray *eh* shot across the screen, and simul-

FIG. 11.

FIG. 12.

taneously the ray *df* shifted its position up to *dg*. The same phenomena were observed when the pole *b* was connected with the coil, and contact was alternately made and broken with *a*; as the ray *dg* shot across, the ray *ef* dipped to *eh*.

These experiments show that two parallel rays of molecules issuing from the negative pole exert lateral *repulsion*, acting like adjacent streams of similarly-electrified bodies. Had they carried an electric current they should have attracted each other, unless, indeed, the attraction in this case was not strong enough to overcome the repulsion.

Many experiments have been made to ascertain the law of the action of magnets and of wires carrying currents, on the stream of molecules.

As an indicator, a small tube, as shown in Fig. 12, was employed. The two poles are at *a* and *b*, *a* being the negative. At *c* is a plate of mica with a hole in its centre, and at *d* is a phosphorescent screen. A sharp image of the hole in the mica is projected on the centre of *d*, and the approach of a magnet causes this bright spot to move to different parts of the phosphorescent screen.

A large electro-magnet was used, actuated by two Grove's cells, and the indicator tube was carried round the magnet in different positions and the results noted. The molecular stream when under no magnetic influence passes along the axis of the tube, as shown by the small arrow (Fig. 12). It will be seen that the indicator can occupy three different directions in respect to the magnet. The magnet being held horizontally, the direction of the molecular stream may be parallel to the axis, tangential to it, or at right angles to it. In either of these positions, also, the stream may be directed one way or the other (by turning the tube round endwise). In these different positions various results are obtained which are easily illustrated with a solid model, but are somewhat complicated to explain by means of flat drawings. They are fully described in the paper.

A long tube was made similar to the small indicator shown in Fig. 12, but having a molecular trajectory six inches long. It was only exhausted to the point at which the image of the spot was just seen sharply defined on the screen, as at higher exhaustions the action of magnetism is less. The phosphorescent screen was divided into squares for convenience of noting the deflection of the spot of light. So sensitive was this to magnetic influence, that when the tube was placed parallel to the earth's equator the earth's magnetism was sufficient to cause the spot to move 5 millims. away from the position it occupied when parallel to the dipping needle (in which position the earth's magnetism did not appear to act). When held equatorially and rotated on its axis, the spot of light, being always driven in one direction independent of the rotation of the tube, appeared to travel round its normal position in a circle of 10 millims. diameter.

I have long tried to obtain continuous rotation of the molecular rays under magnetic influence, analogous to the well-known rotation obtained at lower exhaustions. Many circumstances had led me to think that such rotation could be effected. After many failures an apparatus was constructed as follows, which gave the desired results:—

A bulb (Fig. 13) was blown of German glass, and a smaller bulb was connected to each end of the larger bulb by an open, very short neck. At each extremity was a long aluminium pole projecting partly into the large bulb and turned conical at the end. After good exhaustion the passage of an induction current through this apparatus fills the centre bulb with a very fine green light, whilst the neck surrounding the pole which happens to be negative is covered with two or three dark and bright patches in constant motion, following each other round first one way and then the other, constantly changing direction and velocity, sometimes dividing into other patches, and at others fusing together into one. After a

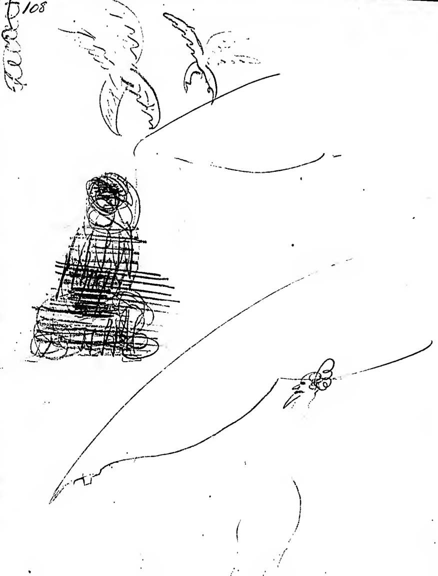
108



... moral between them and their causes. In order to make any progress even in the subordinate task of tracing out the relations of these effects to one another, the inquirer finds it necessary to venture upon hypothesis, and in all metaphysical speculation we sadly miss that healthy discipline with which Nature in other branches of science relentlessly refutes our hypotheses if they are wrong. Here, then, is a region in which the plausible may be mistaken for the true; and it is unfortunately certain that it has sometimes been so mistaken by the ablest human minds.

The biological sciences treat of all the phenomena of living beings, except their mental phenomena, which are those which lie most remote from their causes. Here the complication is less, but it is still too great for the human mind to have yet penetrated behind it. We are still occupied with phenomena which lie at a great distance from their real causes. We are accordingly still far beyond the range of the exact sciences. Most of the great discoveries of biological science have been made by estimating the *general drift* of what is taught by a vast number of particular facts. This, it will be observed, is a kind of reasoning that is necessarily more or less inexact, and, as a consequence, it is one which requires while intellectual training and great experience and tact to handle it with safety. When the investigator has brought these qualifications to his task, astonishing progress has been made in these sciences; without them the reasoning may degrade into being either trivial or loose.

In the rest of the study of Nature we are not embarrassed by the phenomena of life, and many mysteries therefore stand aside out of our path. Here lies the domain of the physical sciences. It is here that the mind of man has best been able to cope with the realities of the universe, and in which its greatest achievements have been effected. It is here that exact reasoning finds a predominant place.

The study of the physical sciences has been remitted by the British Association to its first two sections, chemistry being assigned to Section B, and the rest of the physical sciences to Section A. Accordingly, Section A includes the whole range of mathematics, along with the study of the conditions of rest and motion in that part of matter which is endowed with mass, and of the phenomena of sound, heat, light, and electricity, with the applications of these abstract studies in molecular physics and to astronomy, crystallography, and meteorology.

In meteorology, owing to the complication of the materials that have to be dealt with, we must have frequent recourse to the same kind of reasoning as has been found so effectual in the biological sciences; but in the other physical sciences which I have enumerated exact reasoning prevails, and on this account they are frequently classed together as the exact sciences.

The process of investigation in the exact sciences is fundamentally one in all cases. It has been well described by Mill in the third book of his "Logic." Nevertheless, it is notorious that minds which are well fitted for some branches of physical inquiry find difficulty—sometimes insuperable difficulty—in pursuing others. It is not every eminent mathematician who would have made an equally good chemist, or *vice versâ*. This is because there exists a practical distinction separating the investigation of exact science into two well-marked classes when they are viewed, not as they are in themselves, but in their relation to the powers of us human beings. I refer to the distinction between the experimental method or the method of observation, on the one hand; and the deductive method, or the method of reasoning, on the other. All valid investigations in exact science appeal to what can be directly perceived, and all lead to a conclusion which can be reasoned out from it; but there are some of these investigations in which the main difficulty consists in making the appeal to the senses, and there are others in which the main difficulty lies in the process of reasoning.

To contend with these difficulties successfully requires very different qualities of mind and body. In experimental science the powers principally called into requisition are readiness and closeness of observation, dexterity in manipulation, skill in devising expedients, accuracy in making adjustments, and great patience. It also requires that the investigator should have an accurate memory of what else he has witnessed resembling the phenomenon under observation, that he should be quick to detect every point of agreement and difference that can be perceived, and be skilful to select those which are significant, and to employ them as materials for provision to guide his further proceedings. But the strain on the reasoning powers is generally less, often of trifling amount. The question is put to Nature, and it is Nature usually that gives the bulk of the answer. The most striking monument of splendid achievements by the experimental method of investigation unaided by the deductive method is to be found in the science of chemistry.

An equally typical instance of the power of the deductive method is the science of mechanics. This science, which has sunk deeper into the secrets of Nature than any other science, and which is the science towards whom all other physical sciences are at present more or less gravitating, is essentially deductive. There is little or no difficulty about its fundamental data. They are facts of Nature so patent to all men, and so indelibly implanted in human conception, that some persons have supposed that we have an intuitive perception of them. But, while the materials from which the mind is to work are thus easily obtained, it has taxed to the utmost the reasoning powers of understandings like Newton's to evolve the few consequences of them which are already known; and the investigator has to call to his assistance every aid to prolonged consecutive thought which mathematicians can devise.

In grappling with the problems of Nature we are seldom allowed the choice of the method of investigation we shall employ. This is commonly settled for us and not by us. Where we cannot advance without further information, we must make further observations, *i.e.*, we must employ the experimental method, the appeal *ad experientiam*: where we cannot advance without understanding better what the information we possess really amounts to, we must employ the deductive method.

No reach of intellect applied to the materials in existence before 1860 could have elicited the fact that iron exists upon the sun. This great discovery was made by Professor Kirchhoff, a scientific man who was equally versed in both methods of investigation. On the present occasion it was the experimental method he employed. He applied to the scrutiny of the sun's spectrum four prisms of the most homogeneous glass that could be procured, figured with the greatest accuracy that the eminent artist Steinheil could attain. He expended far more pains on their adjustment for each successive part of the spectrum than any of his predecessors had done, and he was rewarded by a more perfect vision of the sun's glorious spectrum than had met the human eye before. In a collateral inquiry, suggested by an observation made by Foucault, he and Bunsen placed a metallic vapour emitting bright rays in front of a still brighter incandescent body, so that the light from the brighter background had to pass through this vapour, and they found that this vapour now caused dark lines in the spectrum occupying the positions which its own bright lines had before filled. Professor Kirchhoff thereupon added an appliance to his spectroscope which enabled him to bring a metallic spectrum and the solar spectrum together into the field of view, alongside of one another. On accomplishing this he saw sixty of the brightest of the iron rays as continuations of sixty of the strongest of the dark lines in the sun's spectrum; and, by an elaborate scrutiny, he satisfied himself that the observations had been pushed to a sufficient degree of exactness to make sure that a deviation would have been detected in any one of these sixty cases if it had amounted to as much as one-fourth of the average interval between consecutive lines of the solar spectrum. From this it was obvious that the sixty coincidences are not due to chance, but indicate that there is really iron vapour in the path of the rays. It will be observed that Kirchhoff's great merit and the real difficulty of his work lay in the scientific foresight and the industry which were required to frame hypotheses that were worth testing, to guide the investigation by these hypotheses, to contrive, construct, and adjust adequate apparatus, and to make with it the elaborate observations and the exact observations and maps which were necessary. But when by these means the new facts had been brought to light, the inference from them that there is iron in the atmosphere of the sun was an easy one. This example will better convey than a definition what are the characteristic features of an experimental inquiry.

On the other hand, no series of observations or experiments, however skilfully arranged, could have enabled any one to understand the cause of that familiar but truly surprising phenomenon that a top stands upon its peg while it is spinning. But a full explanation of it is within the reach of any student who will train his mind to reason consecutively, and avail himself of the aids to prolonged consecutive thought which mathematicians have contrived. He will then see that the most obvious and familiar mechanical facts involve as necessary consequences all the phenomena which he finds in the schoolboy's top, in the physicist's gyroscope, and in the precision and nutation of the heavens. This, then, is a problem of Nature which falls within the province of the deductive method.

Wherever data are known exactly, these inferences from these data however remote may be depended upon as corresponding with what actually occurs in Nature. And if in such cases the mind of man has proved equal to the task of drawing inferences which can effectually grapple with the problems he finds around him in the universe—which is, alas! as yet but too seldom—then will the deductive method, our plummet, explore depths in the great ocean of existence which our anchors of experiment could not have reached.

The distinction which is here made between deductive and experimental investigations would have no place in a logical system. But it has direct reference to human convenience, and derives its importance from this circumstance. It is obvious, too, that an investigation may partake of both characters—that it may require all the powers of the scientific observer to get at the facts, or even to appreciate them, and all the resources of the mathematician to elicit the consequences of them. For instance, on beginning his electrical studies, the student of Nature must master a mixed experimental and deductive inquiry to get at the elementary fact that free electricity resides either at or outside the surfaces of conductors; and he must engage in a further inquiry, and one only within the reach of a trained mind, to deduce from this the law of the inverse square. And, again, no full appreciation or even intelligent use of the common electrostatic and electrodynamic measures which he meets at the threshold of his electrical studies is within the reach of the mere experimentalist or the mere theorist. And if this treacherous ground lies before the immature student at his entrance, what shall we say of the bogs he struggles into as he advances. We are perpetually meeting with inquiries of this mixed character in electricity and some of the other physical sciences, but they are comparatively rare in either mechanics or chemistry, and none that is difficult lies in the path of the beginner. How many students are there who are made to slur over the above and a multitude of similar difficulties, and who are told that they are learning science, when in fact what they are really learning is the pernicious habit of being content to see Nature through a fog or through other men's mental eyes.

In mechanics valuable progress can be made by the mere mathematician, the student of deductive science; and in chemistry similar progress can be made by the mere experimentalist. Of all the physical sciences these are the most purely deductive, and the most purely experimental. What I desire particularly to invite attention to is that the two great methods of investigation may best be acquired in these two sciences, and that for a really sound grasp of the remaining physical sciences, and especially with a view to further advance in physical science, a command of both methods of investigation is essential.

We must bear in mind, too, that either method of investigation may be misapplied, and that this is a risk carefully to be guarded against. The deductive method when misapplied leads us in speculation, the experimental method becomes empiricism; and it so happens that the sciences of mechanics and chemistry are not only monuments of the power of the two great methods of investigation, but instructive examples of their weakness also. For in chemistry, scarce any attempt at prolonged reasoning, carrying us by any lengthened flight to a distance from the experiments, can be relied on. The result has seldom risen to anything better than speculation. And on the other hand, in mechanics, conclusions which depend on experiments only are empirical; that is, they are deficient in accuracy, and their relation to the other phenomena of the science is left in darkness. Here, then, we find in these two sciences not only how strong these two methods of investigation are, but how weak they may become if misapplied.

I do not know whether any of my predecessors in this chair has experienced so much difficulty, or has hesitated so long and so much as I have hesitated in selecting the topic to which he would ask your attention. My first effort was an attempt to delineate the great recent progress of the mathematical and physical sciences, but it was unsatisfactory, partly from my own too scanty powers, and also because the variety and even disparity of the numerous sciences somewhat arbitrarily grouped together in Section A gave to the outline too sketchy a character. My next attempt was to make a selection among them, confining myself to those with which I am best acquainted, and endeavouring to direct attention to the problems which at the present time seem most to stand in need of solution. But here I felt unwilling either to bring forward or to withhold views which might be disputed. I then applied myself to the single consideration of what I hoped might prove useful and not inopportune at a time when one university, which I trust will prove a great university, is rising in the North of England, and when another university which has carefully and successfully fostered a high standard of education for thirty years, and which has thereby deserved and won the respect of educated men, has just been sacrificed to ecclesiasticism in the sister isle. In this university I have held the most central office for twenty-two years, and in the discharge of my duty had largely to influence its destiny in respect to almost every educational problem. Parliament in its wisdom has now seen fit to destroy this work, and I have not been without hope that from the experience which has been gained some effect which shall last may yet arise, and that the Queen's University may perhaps at its death bequeath a useful legacy to the University of Victoria. The advancement of science in the North of England will largely depend for many years on the wisdom of the regulations for scientific training which are adopted at first by the new university; and I have therefore ventured, at this peculiar juncture, to submit to the judgment of my scientific brethren the principles which much thought and many trials extending over several years have led me to believe should guide them in selecting this part of a curriculum.

I have sought to show that it is in the study of mechanics and in the practice of chemistry that the two great methods of investigation may best be acquired. In them they may be studied separately, by steps of graduated difficulty, and with a superabundance of materials; and each of them supplies the necessary cautions with respect to the method which is all powerful in the other. No scientific man is really equipped for the pursuits in which both methods have to be employed till he has separately acquired a grasp of each. For it is only then that he will be armed against the errors which lead so many to mistake empiricism on the one hand and speculation on the other for solid science, or to underrate solid science mistaking it for speculation. Nor is it only in his scientific occupations that he will derive benefit from this training. All exact reasoning, whether in science or in common life, belongs to these great divisions; and in the numberless instances in which we must be satisfied with reasoning which falls short of being exact, our only safety lies in having by the practice of exact reasoning, both deductive and experimental, attained to that intellectual tact and caution which alone will enable us to handle with safety the sharp and slippery tool. It is thus that a sound judgment with regard to truth may best be acquired by man or woman; and soundness of judgment is the noblest endowment of man's understanding, just as veracity is first among his virtues.

ON RADIANT MATTER.*

By William Crookes, F.R.S.

To throw light on the title of this lecture I must go back more than sixty years—to 1816. Faraday, then a mere student and ardent experimentalist, was twenty-four years old, and at this early period of his career he delivered a series of lectures on the General Properties of Matter, and one of them bore the remarkable title "On Radiant Matter." The great philosopher's notes of this lecture are to be found in Dr. Bence Jones's "Life and Letters of Faraday," and I will here quote a passage in which he first employs the expression Radiant Matter:

"If we conceive a change as far beyond vaporisation as that is above fluidity, and then take into account also the proportional increased extent of alteration as the changes rise, we shall perhaps, if we can form any conception at all, not fall far short of radiant matter; and as in the last

* A lecture delivered to the British Association for the Advancement of Science, at Sheffield, Friday, August 22, 1879.

conversion of many qualities were lost, so here also many more would disappear."

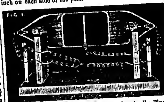
Faraday was evidently engrossed with this far-reaching speculation, for three years later—in 1819—we find him bringing fresh evidence and argument to strengthen his startling hypothesis. His notes are now more extended, and they show that in the intervening three years he had thought much and deeply on this higher form of matter. He first points out that matter may be classed into four states—solid, liquid, gaseous, and radiant—these modifications depending upon differences in their several essential properties. He admits that the existence of radiant matter is as yet unproved, and then proceeds, in a series of ingenious analogical arguments to show the probability of its existence.*

If, in the beginning of this century, we had asked, What is a gas? the answer then would have been that it is matter, expanded and rarefied to such an extent as to be impalpable, save when set in violent motion; invisible, incapable of assuming or of being reduced into any definite form like solids, or of forming drops like liquids; always ready to expand where no resistance is offered, and to contract on being subjected to pressure. Sixty years ago such were the chief attributes assigned to gases. Modern research, however, has greatly enlarged and modified our views on the constitution of these elastic fluids. Gases are now considered to be composed of an almost infinite number of small particles or molecules, which are constantly moving in every direction with velocities of all conceivable magnitudes. As these molecules are exceedingly numerous, it follows that no molecule can move far in any direction without coming in contact with some other molecule. But if we exhaust the air or gas contained in a closed vessel, the number of molecules becomes diminished, and the distance through which any one of them can move without coming in contact with another is increased, the length of the mean free path being inversely proportional to the number of molecules present. The further this process is carried the longer becomes the average distance a molecule can travel before entering into collision; or, in other words, the longer its mean free path, the more the physical properties of the gas or air are modified. Thus, at a certain point, the phenomena of the radiometer become possible, and on pushing the rarefaction still further, *i.e.*, decreasing the number of molecules in a given space and lengthening their mean free path, the experimental results are obtainable to which I am now about to call your attention. So distinct are these phenomena from anything which occurs in air or gas at the ordinary tension, that we are led to assume that we are here brought face to face with matter in a fourth state or condition, a condition as far removed from the state of gas as a gas is from a liquid.

Mean Free Path. Radiant Matter.—I have long believed that a well-known appearance observed in vacuum tubes is closely related to the phenomena of the mean free path of the molecules. When the negative pole is examined while the discharge from an induction coil is passing through an exhausted tube, a dark space is seen to surround it. This dark space is found to increase and diminish as the vacuum is varied, in the same way that the free mean path of the molecules lengthens and contracts. As the one is perceived by the mind's eye to get greater, so the other is seen by the bodily eye to increase in size; and if the vacuum is insufficient to permit much play of the molecules before they enter into collision, the passage of electricity shows that the "dark space" has shrunk to small dimensions. We naturally infer that the dark space is the mean free path of the molecules of the residual gas, an inference confirmed by experiment.

I will endeavour to render this "dark space" visible to all present. Here is a tube (Fig. 1), having a pole in the centre in the form of a metal disc, and other poles at each end. The centre pole is made negative, and the two end poles connected together are made the positive terminal. The dark space will be in the centre. When the exhaustion is not very great the dark space extends only a little on each side of the negative pole in the centre. When the exhaustion is good, as in the tube before you, and I turn on the coil, the dark space is seen to extend for about an inch on each side of the pole.

FIG. 1.



Here, then, we see the induction spark actually illuminating the lines of molecular pressure caused by the excitement of the negative pole. The thickness of this dark space is the measure of the mean free path between successive collisions of the molecules of the residual gas. The extra velocity with which the negatively electrified molecules rebound from the excited pole keeps back the more slowly moving molecules which are advancing towards that pole. A conflict occurs at the boundary of the dark space, where the luminous margin bears witness to the energy of the discharge.

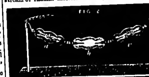
Therefore the residual gas—or, as I prefer to call it, the gaseous residue—within the dark space is in an entirely different state to that of the residual gas in vessels at a lower degree of exhaustion. To quote the words of our last year's President, in his address at Dublin:

"In the exhausted column we have a vehicle for electricity not constant like an ordinary conductor, but itself modified by the passage of the discharge, and perhaps subject to laws differing materially from those which it obeys at atmospheric pressure."

In the vessels with the lower degree of exhaustion, the length of the mean free path of the molecules is exceedingly small as compared with the dimensions of the bulb, and the properties belonging to the ordinary gaseous state of matter, depending upon constant collisions, can be observed. But in the phenomena now about to be examined, so high is the exhaustion carried that the dark space around the negative pole has widened out till it entirely fills the tube. By great rarefaction the mean free path has become so long that the hits in a given time in comparison to the misses may be disregarded, and the average molecule is now allowed to obey its own motions or laws without interference. The mean free path, in fact, is comparable to the dimensions of the vessel, and we have no longer to deal with a continuous portion of matter, as would be the case were the tubes less highly exhausted, but we must here contemplate the molecules individually. In these highly exhausted vessels the molecules of the gaseous residue are able to dart across the tube with comparatively few collisions, and radiating from the pole with enormous velocity, they assume properties so novel and so characteristic as to entirely justify the application of the term borrowed from Faraday, that of radiant matter.

Radiant Matter exerts Powerful Phosphorogenic Action where it Strikes.—I have mentioned that the radiant matter within the dark space excites luminosity where its velocity is arrested by residual gas outside the dark space. But if no residual gas is left, the molecules will have their velocity arrested by the sides of the glass; and here we come to the first and one of the most noteworthy properties of radiant matter discharged from the negative pole—its power of exciting phosphorescence when it strikes against solid matter. The number of bodies which respond luminously to this molecular bombardment is very great, and the resulting colours are of every variety. Glass, for instance, is highly phosphorescent when exposed to a stream of radiant matter. Here (Fig. 2) are three bulbs

FIG. 2.



composed of different glass: one is uranium glass (*a*), which phosphoresces of a dark green colour; another is English glass (*b*), which phosphoresces of a blue colour; and the third (*c*) is soft German glass—of which most of the apparatus before you is made—which phosphoresces of a bright apple-green.

My earlier experiments were almost entirely carried on by the aid of the phosphorescence which glass takes up when it is under the influence of the radiant discharge; but many other substances possess this phosphorescent power in a still higher degree than glass. For instance, here is some of the luminous sulphide of calcium prepared according to M. Ed. Becquerel's description. When the sulphide is exposed to light—even candlelight—it phosphoresces for hours with a bluish white colour. It is, however, much more strongly phosphorescent to the molecular discharge in a good vacuum, as you will see when I pass the discharge through this tube.

Other substances, besides English, German, and uranium glass, and Becquerel's luminous sulphides, are also phosphorescent. The rare mineral phenakite (aluminate of glucinum) phosphoresces blue; the mineral spodumene (a silicate of aluminium and lithium) phosphoresces a rich golden yellow; the emerald gives out a crimson light. But without exception, the diamond is the most sensitive substance I have yet met for ready and brilliant phosphorescence. Here is a very curious fluorescent diamond, green by daylight, colourless by candlelight. It is mounted in the centre of an exhausted bulb (Fig. 3), and the molecular

FIG. 3.

discharge will be directed on it from below upwards. On darkening the room you see the diamond shines with as much light as a candle, phosphorescing of a bright green.

Next to the diamond the ruby is one of the most remarkable stones for phosphorescing. In this tube (Fig. 4) is a

FIG. 4.

fine collection of ruby pebbles. As soon as the induction spark is turned on you will see these rubies shining with a brilliant rich red tone, as if they were glowing hot. It scarcely matters what colour the ruby is, to begin with. In this tube of natural rubies there are stones of all colours—the deep red and also the pale pink ruby. There are some so pale as to be almost colourless, and some of the highly-prized tint of pigeon's blood; but under the impact of radiant matter they all phosphoresce with about the same colour.

Now the ruby is nothing but crystallised alumina with a little colouring matter. In a paper by Ed. Becquerel,* published twenty years ago, he describes the appearance of alumina as glowing with a rich red colour in the phosphoroscope. Here is some precipitated alumina prepared in the most careful manner. It has been heated to whiteness, and you see it also glows under the molecular discharge with the same rich red colour.

The spectrum of the red light emitted by these varieties of alumina is the same as described by Becquerel twenty years ago. There is one intense red line, a little below the fixed line B in the spectrum, having a wave-length of about 6895. There is a continuous spectrum beginning at about B, and a few fainter lines beyond it, but they are so faint in comparison with this red line that they may be neglected. This line is easily seen by examining with a small pocket spectroscope the light reflected from a good ruby.

There is one particular degree of exhaustion more favourable than any other for the development of the properties of radiant matter which are now under examination. Roughly speaking it may be put at the millionth of an atmosphere.† At this degree of exhaustion the phosphorescence is very strong, and after that it begins to diminish until the spark refuses to pass.‡

* "I may now notice a curious progression in physical properties accompanying changes of form, and which is perhaps sufficient to induce, in the inventive and sanguine philosopher, a considerable degree of belief in the association of the radiant form with the others in the set of changes I have mentioned.

"As we ascend from the solid to the fluid and gaseous states, physical properties diminish in number and variety, each state losing some of those which belonged to the preceding state. When solids are converted into fluids, all the varieties of hardness and softness are necessarily lost. Crystalline and other shapes are destroyed. Opacity and colour frequently give way to a colourless transparency, and a general mobility of particles is conferred.

"Passing onward to the gaseous state, still more of the evident characters of bodies are annihilated. The immense differences in their weight almost disappear; the remains of differences in colour that were left, are lost. Transparency becomes universal, and they are all elastic. They now form but one set of substances, and the varieties of density, hardness, opacity, colour, elasticity and form, which render the number of solids and fluids almost infinite, are now supplied by a few slight variations in weight, and some unimportant shades of colour.

"To those, therefore, who admit the radiant form of matter, no difficulty exists in the simplicity of the properties it possesses, but rather an argument in their favour. These persons show you a gradual resignation of properties in the matter we can appreciate as the matter ascends in the scale of forms, and they would be surprised if that effect were to cease at the gaseous state. They point out the greater exertions which nature makes at each step of the change, and think that, consistently, it ought to be greatest in the passage from the gaseous to the radiant form."—*Life and Letters of Faraday*, vol. i., page 308.

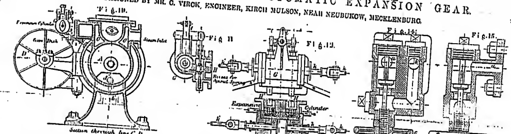
HORIZONTAL ENGINE WITH AUTOMATIC EXPANSION GEAR.

DESIGNED BY MR. C. VIRCK, ENGINEER, KIRCH MULSON, NEAR NEUBUKOW, MECKLENBURG.



steam space. They receive their movement by levers e and e¹, which engage at their one end with the valve spindles f and f¹, and at the other ends, which are provided with rollers to lessen friction and abrasion, with cams g and g' on the discs D and D¹. These discs are keyed on the shaft E, which is driven direct from the crank-shaft F by the bevel wheels a and a¹, and which makes the same number of revolutions as the engine itself. The levers e and e¹¹ are connected by the rod l, and if either of the two valves opens the other must shut, and vice versâ. (See also Figs. 1, 3, 4, 5, and 10.) By choosing a proper shape for the cams g and g¹, and a corresponding lap for the valves, a prompt motion, a correct compression, and a timely release can be easily obtained.

The steam valves are also worked, as far as their opening is concerned, by levers e¹ and e¹¹¹, which are of the same design as the levers e and e¹¹, and the cams f and f¹ on the discs D and D¹, but their closing is effected, at the proper instant, by a small steam cylinder G called the "expansion cylinder," and which is shown to an enlarged scale in Figs. 11, 12, and 13. It has two slide valves i and i¹, which are so connected with each other that if the one opens the other closes, and vice versâ, and which work in two separate steam chests II and II¹, these being placed in communication with the corresponding ends of the main steam cylinder A by two steam pipes z and z¹. The rods k and k¹, when they are moving outwards, can not engage with the levers e and e¹, on account of the slots y and y¹ at the ends of these rods, but when they are moving inwards the ends of the slots take hold of the pins x and x¹, and the levers must follow the movement of the rods, and the valves c and c¹ are closed.

If now the valve i of the expansion cylinder G be opened after the piston C of the main steam cylinder has made part of its stroke towards the left, steam will enter G from A, and the piston rod k will move inwards, and by imparting motion to the lever e¹ will shut the steam valve c, and the expansion in the main cylinder will begin; while if the valve i remains open until the end of the stroke, the steam, which has worked in the expansion cylinder at full boiler pressure, will expand back into the main cylinder. If now the valve i still remains open during the return stroke, the expanded steam in the expansion cylinder will find its way out through this very same valve into the main exhaust, and only when the expansion for the return stroke is initiated by the opening of the valve i¹, and the simultaneous closing of i, the communication between the two cylinders will be interrupted at this side, and reopened at the opposite one.

Such a motion of the valves as just described is automatically imparted to them by the governor H (see Figs. 3, 4, 6, and 7) which may have any speed most suitable to its construction, but the spindle n, which receives its rotation from the governor shaft by a pair of spur wheels, must make the same number of revolutions as the engine itself. On the top end it carries a sleeve o, with a cam r, which, on account of a spiral face worked on the upper part of the spindle a, must change its angular position when it is lifted or lowered by the governor; but if the governor does not alter the position of the sleeve, the cam simply participates in the rotation of the spindle n, and its position on it is so adjusted, that during each stroke of the engine the cam r strikes once against the frame p, and, by means of the connexions q, r, s, t, w, and w¹, acts on the valves i and i¹, opening the one and shutting the other. This will take place according to the height of the governor balls, and (on account of the spiral face on which the sleeve has to slide) sooner or later after the commencement of the stroke; the governor thus completely controls the expansion of the engine, and a correct and quick cut-off, varying from 0.03 to 0.8 of the stroke, can be obtained.

To gradually reduce the speed of the steam valves after they have closed their ports, and to prevent a shock, two steam dashpots, P and P¹ (which are cast together with the steam chests II and III) are provided, and the valve for regulating their action are shown in Figs. 14 and 15. The steam passage a, communicates with the dash-pot, and the passage b with the steam chest, and the two small handwheels c and d serve to fix the valve in its proper position.

The expansion cylinder need only be made very small, as only the friction resulting from the stuffing boxes and the dead weights has to be overcome, and the cubical contents of it and its piping will always be but a small fraction of the necessary space between the piston and the cylinder cover of the engine.

The draining of the cylinder is effected at each stroke when the exhaust port is open through a hole or recess in the end, at the bottom of the exhaust valve, see Figs. 1 and 10, and a bridge in the centre of the port prevents the escape of the steam through this opening when the valve is closed.

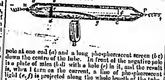
ON RADIANT MATTER.*

By WILLIAM CROOKES, F.R.S.

(Concluded from page 168.)

Radiant Matter is deflected by a Magnet.—I now pass to another property of radiant matter. This long glass tube (Fig. 14) is very highly exhausted; it has a negative

FIG. 14.



pole at one end (a) and a long phosphorescent screen (b c) down the centre of the tube. In front of the negative pole is a plate of mica (b d) with a hole (e) in it, and the result is, when I turn on the current, a line of phosphorescent light (e, f) is projected along the whole length of the tube. I now place beneath the tube a powerful horseshoe magnet: observe how the line of light (e, g) becomes curved under the magnetic influence, waving about like a flexible wand as I move the magnet to and fro.

This action of the magnet is very curious, and if carefully followed up will elucidate other properties of radiant matter. Here (Fig. 15) is an exactly similar tube, but

FIG. 15

having at one end a small potash tube, which if heated will slightly injure the vacuum. I turn on the induction current, and you see the ray of radiant matter tracing its trajectory in a curved line along the screen, under the influence of the horseshoe magnet beneath. Observe the shape of the curve. The molecules shot from the negative pole may be likened to a discharge of iron bullets from a mitrailleuse, and the magnet beneath will represent the earth curving the trajectory of the shot by gravitation. Here on this luminous screen you see the curved trajectory of the shot accurately traced. Now suppose the deflecting force to remain constant, the curve traced by the projectile varies with the velocity. If I put more powder in the gun the velocity will be greater and the trajectory flatter, and if I interpose a denser resisting medium between the gun and the target, I diminish the velocity of the shot, and thereby cause it to move in a greater curve and come to the ground sooner. I cannot well increase before you the velocity of my stream of radiant molecules by putting more powder in my battery, but I will try and make them suffer greater resistance in their flight from one end of the tube to the other. I heat the caustic potash with a spirit-lamp and so throw in a trace more gas. Instantly the stream of radiant matter responds. Its velocity is impeded, the magnetism has longer time on which to act on the individual molecules, the trajectory gets more and more curved, until, instead of shooting nearly to the end of the tube, my molecular bullets fall to the bottom before they have got more than half way.

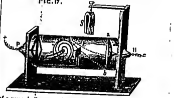
It is of great interest to ascertain whether the law governing the magnetic deflection of the trajectory of radiant matter is the same as has been found to hold good at a lower vacuum. The experiments I have just shewn you were with a very high vacuum. Here is a tube with a low vacuum (Fig. 16). When I turn on the induction

FIG. 16.

spark, it passes as a narrow line of violet light joining the two poles. Underneath I have a powerful electro-magnet. I make contact with the magnet, and the line of light dips in the centre towards the magnet. I reverse the poles, and the line is driven up to the top of the tube. Notice the difference between the two phenomena. Here the action is temporary. The dip takes place under the magnetic influence; the line of discharge then rises and pursues its path to the positive pole. In the high exhaustion, however, after the stream of radiant matter had dipped to the magnet it did not recover itself, but continued its path in the altered direction.

By means of this little wheel, skilfully constructed by Mr. Gimingham, I am able to show the magnetic deflection in the electric lantern. The apparatus is shown in this diagram (Fig. 17). The negative pole (a, b), is in the form

FIG. 17.



of a very shallow cup. In front of the cup is a mica screen (c, d), wide enough to intercept the radiant matter coming from the negative pole. Behind this screen is a mica wheel (e, f), with a series of vanes, making a sort of paddle-wheel. So arranged, the molecular rays from the pole a b will be cut off from the wheel, and will not produce any movement. I now put a magnet g over the tube, so as to deflect the stream over or under the obstacle c d, and the result will be rapid motion in one or the other direction, according to the way the magnet is turned. I throw the image of the apparatus on the screen. The spiral lines painted on the wheel show which way it turns. I arrange the magnet to draw the molecular stream so as to beat against the upper vanes, and the wheel revolves rapidly as if it were an overshot water-wheel. I turn the magnet so as to drive the radiant matter underneath; the wheel slackens speed, stops, and then begins to rotate the other way, like an undershot water-wheel. This can be repeated as often as I reverse the position of the magnet.

I have mentioned that the molecules of the radiant matter discharged from the negative pole are negatively electrified. It is probable that their velocity is owing to the mutual repulsion between the similarly electrified pole and the molecules. In less high vacua, such as you saw a few minutes ago (Fig. 16), the discharge passes from one

* A lecture delivered to the British Association for the Advancement of Science, at Sheffield, Friday, August 22, 1879.

ACTION OF MAGNETISM ON THE RADIOMETER.

Engl. Mechanic Oct 17 1879

IN a recent number of Wiedemann's *Beiblätter*, some instructive experiments with the radiometer by Herr Basso are described.

Into the magnetic field of a strong electro-magnet Herr Basso brought an ordinary radiometer with four mica vanes blackened on one side, and let the rays of a gas-flame fall on it at first alone, and until it attained a constant velocity; then he closed the circuit of the electro-magnet so that the action of this was added to that of light. The result was that the constant velocity diminished (in one experiment, *e.g.*, in a ratio of 25 : 20¾). This retardation was chiefly caused, the author says, by the action of the poles of the large magnet on the vanes, perhaps also by magnetic action on the residual air contained in the radiometer, of which the oxygen is strongly magnetic, and by the production of electric currents through motion of the radiometer in presence of the magnetic pole.

The existence of induction currents in connection with the retardation appeared somewhat probable, because the retardation caused by magnetism was especially great (comparatively) in the case of a radiometer with metallic cross and metallic vanes.

A simple two-armed radiometer, with aluminium arms and mica veins, of which latter the one had one uncoated and one black side, while the two surfaces of the other were uncoated, stood still in darkness in the field of an unexcited electro-magnet, but turned quickly into the axial position as soon as the magnet was excited. The same radiometer showed a considerable retardation of the rotation produced by light whenever the action of magnetism was superadded.

Herr Basso also sought to measure the force which drives a body in rarefied air away from the light source. He did so by means of a differential radiometer consisting of a horizontal tube 21mm. in length, having glass globes blown at the ends. In the middle of the interior (which was rarefied of air) a vertical steel point supported an aluminium beam, the extremities of which were formed by vertical aluminium plates blackened on the same side, and situated exactly in the middle of the globes. When both vanes were simultaneously struck by rays of equal intensity there was no deflection. When one vane was exposed simply to the action of light, the other merely to magnetic action, these two forces tended, when the axis of the apparatus was at right angles to that of the electro-magnet, to deflect the balance in opposite directions. In this ways, *e.g.*, the flame of an ordinary stearine candle at 21ctm. distance proved equivalent in action to the magnetic action of the electro-magnet at 32mm. distance.

Mr. Crookes on Radiant Matter.

1880 Morning [illegible] Jany

A few weeks since Mr. William Crookes, F. R. S., gave at the London Institution an experimental demonstration of recent researches on radiant matter. He observed that modern research during the last sixty years had greatly enlarged and modified our views on the constitution of gases, which were now believed to be composed of small particles or molecules that were constantly moving in every direction with velocities of all conceivable magnitudes. As these molecules were exceedingly numerous, it followed that no molecule could move far in any direction without coming in contact with some other molecule; but if we exhausted the air or gas contained in a closed vessel, the number of molecules became diminished, and the distance through which any of them could move without coming in contact with another was increased, the length of the mean free path being inversely proportional to the number of molecules present. The further this process was carried, the longer became the average distance a molecule could travel before entering into collision; or, in other words, the longer its mean free path, the more the physical properties of the gas or air were modified. Thus, at a certain point the phenomena of the radiometer became possible, and on pushing the rarefaction still further—*i.e.*, decreasing the number of molecules in a given space and lengthening their mean free path—the experimental results were obtainable, to which Mr. Crookes called the attention of his audience, and which were fully explained in a lecture delivered by him to the British Association at Sheffield in August last.

So distinct, he remarked, were these phenomena from anything which occurred in air or gas at ordinary tension, that we were led to assume that we were here brought face to face with matter in a fourth state or condition—a condition as far removed from the state of gas as gas was from a liquid. In some of its properties radiant matter was as material as wood or tin, while in other properties it almost assumed the character of radiant energy. We had actually touched the borderland where matter and force seem to merge into each other—the shadowy realm between known and unknown, which for him had always had peculiar temptations. He ventured to think that the greatest scientific problems of the future would find their solution in this borderland, and even beyond; there, it seemed to him, lay ultimate realities, subtle, far-reaching and wonderful.

EXPERIMENTAL RESEARCHES IN ELECTRICITY[1]

SUPPLEMENT TO PART III.—*The Electric Condition of the Terminals of a Vacuum-Tube after their connection with the Source of Electricity has been broken*

THE question has been mooted whether there is a polarisation of the terminals of a vacuum-tube after the discharge through it has been interrupted by breaking connection between it and the source of electricity. This question is to be understood in the sense—does there exist a *chemical* polarisation as is the case for instance with the terminals of a voltameter under similar circumstances?

The problem is by no means easy of solution. The authors believe, however, that the few experiments they describe, selected from a long series, will show that there is really no such polarisation of the terminals.

In the first instance the case of the voltameter is considered; the arrangement of the apparatus employed in the experiments is shown in Fig. 1, where K K′ represent

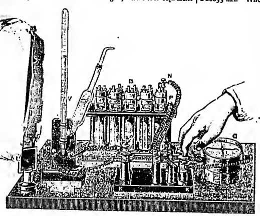


FIG. 1.

a special key for breaking connection between any piece of apparatus and the battery, B, and connecting it afterwards instantaneously with a galvanometer, G. The terminals of the battery are attached respectively to the screw-clamps, *c* and *d*, carried by an ebonite bar, supported on two ebonite columns, touch-points in metallic contact with *c* and *d*, pass through this bar, so that when the brass springs, *a c* and *b f*, are allowed to rise and press against these touch-points, the battery is in metallic connection with the screw-clamps, *a* and *b*, and any piece of apparatus attached to them, as, for example, the voltameter, V. The voltameter employed has a resistance of 20 ohms; its platinum electrodes are 2·5 inches long and 0·025 inch in diameter, and are separated 0·25 inch; it is charged with dilute pure sulphuric acid in the proportion of 1 volume of acid, sp. gr. 1·84, to 8 volumes of water. When the springs are suddenly pressed down by the fingers placed on the ebonite disks, *e* and *f*, the connection is broken between the voltameter and the battery, and it is connected instantaneously with the galvanometer G. The galvanometer actually employed was not that shown in the figure, but a Thomson galvanometer, whose constant

$$C_1 = \frac{1 \text{ volt}}{1 \text{ megohm}} = 1{,}874 \text{ scale divisions.}$$

On connecting a battery of 10 chloride of silver cells with the voltameter for a minute or less, and then suddenly pressing down the springs *e* and *f*, there was a deflection to the left, say, of more than 1000 scale divisions, although the $\frac{1}{999}$ shunt was used to reduce the current through the galvanometer; therefore, the deflection without the shunt would have been more than 1,000,000 divisions. By comparing this deflection with that produced by a half microfarad condenser, charged with 240 cells, it was ascertained that the deviation produced by the voltameter was equivalent to that of 111 microfarads.

The small condenser shown at C, Fig. 1, was substituted for the voltameter; it is made of a thin plate of glass inches square and 0·0115 inch thick; the tinfoil coating being 1·5 inch square, its capacity was found to be 0·00055 m.f. When charged with 3,600 cells, and afterwards connected with the Thomson galvanometer through the $\frac{1}{9}$ shunt, by pressing down *e* and *f*, the deflection was 136·5 divisions to the left; this multiplied by 9·92, the value of the shunt was equivalent to 1,354 divisions.

The apparatus, shown in Fig. 2, which was constructed for another object already described,[1] was connected with *a* and *b*; it consists essentially of two disks, 3·1 inches diameter placed 0·13 inch apart. The capacity of this apparatus, when used as an air-condenser, was determined, and found to be 0·000058 m.f. With 3,600 cells no discharge took place, and it merely charged up as a condenser. The deflection produced, when the keys *e* and *f* were pressed down, was (without shunt) 150 divisions, still to the left. It is evident, therefore, that the direction of the deviation throws no light on the question, for it is the same with the voltameter as with the condenser.

Tube 73, containing a residuum of acetylene, was now substituted for the air-condenser; it is 26·5 inches long and 1·5 inch diameter, the distance between the termals 23 inches; the tube was connected with 3,600 cells, current 0·00681 W. The tube potential was found to be 2,980 cells, and its resistance 449,50[…] ohms. On pressing down the springs *e* and *f*, so as to break connection with the battery and connect the tube with the galvanometer, there was a deflection of 11 divisions to the left, the same as before. The current was only

$$\frac{11}{1874 \times 1{,}000{,}000} = \frac{1}{170{,}000{,}000} \text{ W.}$$

The diagram, Fig. 3, will illustrate the action of the special key, Fig. 1. When the handle is moved to the left, the tube T T′ is placed in metallic connection with the battery, whose terminals are shown attached to *c* and *d* (this is equivalent to the springs being allowed to press upwards against *c* and *d*, Fig. 1); when the handle is moved to the right, then the discharge of the battery through T T′ ceases, and the terminals of the tubes N and P are connected with the galvanometer, the extremities of whose coil are attached to *e* and *f* (this is equivalent to pressing down the springs in Fig. 1).

On another occasion with the same tube, No. 73, wi[…]

[1] "Experimental Researches on the Electric Discharge with the Chloride of Silver Battery," by Warren De La Rue, M.A., D.C.L., F.R.S., and Hugo W. Müller, Ph.D., F.R.S.

[1] *Phil. Trans.*, vol. clxxi. p. 76; NATURE, vol. xxii. p. 152.

a discharge from 2,400 cells, the deviation to the left on passing down *e* and *f* was 20 divisions.

Tube 199, with a hydrogen charge, was now substituted; pressure 2 millims., 2,632 M, 5,100 cells, current 0·01639 W. This tube has already been described (NATURE, vol. xxii. p. 176); it is 37 inches (94 centims.) long, and $5\frac{13}{16}$ inches (14·8 centims.) in diameter. The distance between the terminals, a ring and a straight wire, is 33·5 inches (85 centims.). In the first place the battery was connected direct to the galvanometer, the positive to *e* and the negative to *f* (that is, in the same direction as if the positive were attached to *c* and the negative to *d*). A short piece of wire was inserted between *e* and *f* as a shunt, and the $\frac{1}{999}$ shunt was also used with the galvanometer, the direction of deviation was found to be to left, which it was desired to know.

On pressing down *e* and *f*, the deviation was to the left, and only amounted to 2 divisions. On another occasion, at the same pressure, 3,900 cells, current 0·02925 W., the deviation to the left on pressing down *e* and *f* was from 3 to 5 divisions.

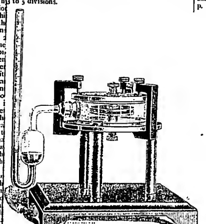

FIG. 2.

to obtain a vacuum vessel with large terminals. The terminals are two disks a little over $4\frac{1}{3}$ inches (11 centims.) in diameter, and in the first instance were placed 3 inches (7·62 centims.) apart. Pressure 4·5 millims., 5,921 M, 2,400 cells, current 0·04366 W., deviation on connecting the disks with the galvanometer, 10 divisions to left.

With 1,200 cells, no discharge took place, but on connecting the galvanometer a deviation of 27 divisions to the left was, nevertheless, produced.

At a pressure of 20 millims., 26,316 M, with 3,900 cells, no current passed, but the deviation on connecting the galvanometer, was 66·6 divisions to the left.

The disks were now placed at a distance of 2 inches (5·08 centims.), the pressure being still 20 millims., and the battery 3,900 cells, the discharge now took place, current 0·03896 W., deflection on connecting galvanometer 8·5 to left.

On reducing the battery to 2,400 cells, the discharge did not take place, but a deviation of 43 divisions was produced on pressing down *e* and *f*.

The same tube, with a charge of coal-gas, pressure 3 millims., 3,947 M, current 0·01705 W., deflection, on pressing down *e* and *f*, 7 divisions to left.

The same tube, with air, pressure 1·5 millims., 1,974 M, current 0·02728 W., on pressing down *e* and *f*, deviation 20 divisions. The deviation was, therefore, greatest with air; but if due to a chemical polarisation, it would have been *a priori* expected to be greatest with coal-gas, which is a mixture of decomposable molecules. The result of the experiments with tube 199 gave the following deviations:—

Hydrogen.		Coal-gas.		Air.
3	... ...	7	... ...	20

Again, tube 199, 2,400 cells, pressure 1 millim., 1,316 M, current 0·02456 W., deflection on pressing down the keys, 16 to left; with 1,500 cells no discharge, yet a deflection of 10 divisions to the left was produced on pressing down the keys. The deflection in the latter case being clearly due to a static charge.

Experiments were now made in air with an apparatus similar to that already described in NATURE, vol. xxii. p. 174, but with disks instead of points, in order

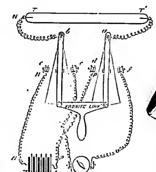

FIG. 3.

The disks were placed at 1 inch (2·54 centims.) apart, same pressure, with 3,900 cells, the current was 0·04201 W., deviation to left on connecting the galvanometer 13 divisions.

2,400 cells would not pass, but a deviation to the left of 47 divisions was obtained on connecting the galvanometer.

The following are the results of these experiments with the disks at various distances:—

Distance, inches.		No. of cells.		Pressure, mm.		Current.		Deflection on connecting galvanometer, divisions.
3	...	1,200	...	4·5	...	did not pass	...	27·0
3	...	2,400	...	4·5	...	passed	...	10·0

1	...	2,400	...	20·0	...	did not pass	...	47·0

So that in every case when the current had not passed

EDISON'S VACUUM APPARATUS.

With the exception of the peculiar carbon used by Mr. Edison in the construction of his lamps, there is nothing of more vital importance in the development of his system of electric illumination than the apparatus employed to exhaust the air from the little globes containing the carbon horseshoes, for upon the perfection of the vacuum depends the success of the lamp.

Since Otto Von Guericke invented the air pump in 1650 it has been the subject of various modifications and improvements; but the most perfect forms of piston air pump yet devised are incompetent to produce the degree of exhaustion demanded by modern experimenters.

In vacuum apparatus, as in most things connected with scientific investigation and experiment, the simplest means and methods prove the best. It seems that in the natural course of invention, simplicity is the latest feature attained. Air pumps and vacuum apparatus form no exception to this general truth. The most recent as well as the most perfect air pumps consist essentially of a glass tube and a column of mercury. Two forms of mercurial pump are used by Mr. Edison in removing the air from his lamp bulb; one for exhausting the greater volume of air, the other for perfecting the vacuum. The first is the invention of Geissler; the second, of Sprengel. The engraving shows the arrangement of these pumps in connection with the McLeod gauge, and other accessories.

Several sets of this apparatus are employed by Mr. Edison, and he has so far improved their construction and working as to enable the attendant to produce very high vacua in twenty-five minutes.

The Geissler pump, A, the Sprengel pump, B, and the McLeod gauge, C, are all connected with the socket that receives the lamp bulbs, through the bulb, E, which is partly filled with phosphorous anhydride—a powerful absorbent of moisture—and through the bulb, F, which contains gold leaf to absorb traces of mercurial vapor. Each set of apparatus is secured to a vertical board, behind which on a bracket near the top sets a reservoir of mercury, which supplies the Sprengel pump, B, through the flexible tube, a, and through a vertical glass tube, having at the top a trap, b, for receiving any air that may be carried by the mercury.

The Sprengel pump, E, consists of a glass tube about ⅛ inch in internal diameter and 36 inches in length, dipping at its lower end into mercury contained in the small vessel resting on the bracket, and having an overflow connected by a flexible tube with a mercury receiver. At the upper end of the ⅛ inch tube is formed a bulb, into which the mercury supply tube enters through a sealed joint (described elsewhere) and extends about two-thirds of the way down the bulb. The bulb is provided with a lateral tube by which it is connected with the Geissler tube, D, and with the bulbs, E and F, which communicate with the lamp bulbs, G. The Sprengel pump also connects with the Geissler pump, A, when the stopcock, c, is open.

The Geissler pump, A, is simply a glass tube, having a bulb blown in it, and communicating at its lower end with a mercury reservoir through a flexible tube, and connecting at its upper end with the Sprengel pump, B, as before described, and also with a bent discharge tube, d, of small caliber, which extends downward something over 30 inches and dips into mercury contained in a small cup provided with an overflow.

The McLeod gauge is no more complicated than either of the pumps. It consists of a bulb, c, blown on the end of a tube of small diameter, and having a still smaller tube, f, projecting from its upper surface. This tube is closed at the top, and its capacity bears a certain ratio to that of the bulb. It extends over the face of a scale, f. The longer and larger tube of the gauge is connected by a flexible tube with the mercury bottle seen resting on the bracket; and it is also connected by a small tube, g, with the system of tubes that connects the two pumps, the Geissler tube, and the lamp bulbs. The connecting tube, g, extends over the scale, f, parallel to and near the gauge tube, f'.

To produce a vacuum in the bulbs, G, the pinch-cock on the rubber pipe, a, is opened so as to permit a rapid succession of drops, or a full stream of mercury to flow down the internal tube of the Sprengel pump, B. This stream of mercury, falling through the space between the internal tube and the lower end of the bulb, enters the long tube of the pump, and carries with it a certain quantity of air, which is discharged together with the mercury into the cup at the bottom. As this process is too slow for creating a vacuum from the beginning, while the Sprengel pump is still working, the Geissler pump, A, is brought into use for removing the greater portion of the air. To operate this pump, the stopcock, c, is first closed, the reservoir of mercury—connected with the pump by a rubber tube—is raised by the attendant, as represented in the cut, until mercury flows up the long pump tube, and filling the bulb, drives out the air before it through the discharge tube, and finally overflows through the tube, d, into the cup at the lower end of the tube. The mercury reservoir is then lowered until the two vertical columns of mercury break in the bend of the discharge tube, and the mercury in the pump is below the stopcock, c, the latter is then opened, and the mercury reservoir is lowered until the mercury in the pump will sink no farther. The stopcock, c, is then closed and the operation is repeated two or three times. The Sprengel pump, which has been in operation meanwhile, is now permitted to finish the work. As the vacuum becomes more and more perfect the mercury rises in the pump, and when the drops strike the mercury column, a sharp metallic clink is heard, indicating that the atmospheric resistance to the falling metal is little or nothing. As fast as the mercury accumulates in sufficient quantities in the reservoir below, it is poured into the reservoir above.

Electric sparks from an induction coil are continually passed through the Geissler tube, D, as long as the vacuum is low enough to admit of it. Mr. Edison says that when a 9 inch spark fails to pass the ⅛ inch space between the electrodes in the tube the vacuum is still coarse.

The McLeod gauge is relied on mainly for testing the perfection of the vacuum. This gauge is operated by simply raising the mercury reservoir connected with it until the gauge bulb is sealed off from the other parts of the apparatus, the mercury, as it rises, closing the connecting tube, g. The mercury reservoir is then raised still further, until the mercury will go no higher in the gauge tube, f'. Should the mercury rise to the end of the gauge tube it would indicate a perfect vacuum, but this is never attained. The quantity of air contained in the tube, f', indicates exactly the proportion of the air in the apparatus to the capacity of the apparatus or air at its normal density. Another method of calculating the value of the vacuum is based upon the difference in the level of mercury in the two tubes in front of the scale, f.

Mr. Edison informs us that the vacuum in his lamps is so nearly perfect that only a millionth of the original volume of air remains.

It is obvious that the Sprengel and Geissler pumps must be longer than a barometer, to obtain the full effect of the falling column of mercury. All of the rigid parts of this apparatus are made of glass, and wherever there is a joint or a stop cock, it is sealed with mercury. Figure 2 shows the upper portion of the Sprengel pump in detail, and also gives a good idea of the manner of sealing the joints. The bulb, H, has a conical mouth, I, into which is fitted and ground the enlarged portion, J, of the mercury tube, K. The space in the mouth, I, above the enlarged part of the tube, K, is filled with mercury.

Figure 3 represents a mercury-sealed stop cock, L being the stop cock, entirely surrounded by mercury contained in the cup, M.

The lamp bulbs, G, are connected with the apparatus by a joint similar to that represented in figure 2. From time to time, while the air is being exhausted from the lamps, they are tested by connection with wires from the electrical generator. When the vacuum is practically complete, the tubes connecting the lamps with the vacuum apparatus are heated by a spirit lamp, sealed and separated from each other and from the apparatus.

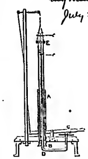
A MERCURIAL AIR-PUMP.

[17011.]—Several letters have lately appeared in the E.M. relative to the exhaustion of vacuum tubes and other small philosophical apparatus, and the best pumps for effecting their exhaustion successfully.

I herewith send a sketch and description of a

Eng Mechanic
July 23 1880



pump which I designed some short time ago. It combines the principle of the mercurial air-pump with that of the ordinary pump with barrel and piston, and being made of glass tubes and wood, with the exception of the valves, any amateur could construct one for himself with ease.

A is a wide glass tube, about 20in. in length, and closed at its lowest extremity by a perfectly-fitting indiarubber cork B. Through this, and up the centre of A, passes a small-bore tube C D, also of glass, the length of which, from C to the cork B, must be a little over 30in. Its lowest end is bent twice, at right angles, and the end *d* projects above the stand, and to it the tubes to be exhausted are fixed. Over this smaller tube, and inside A (i.e., between the two), slides another glass tube E F, contracted at its upper end, and having a band at E fixed to it, by which it can be raised and lowered by the string, which passes over the pulleys, and is attached to the lever G, as shown in the sketch.

The tubes C D and E F are closed at their upper ends by discs, or valves, *r r*, which fit air-tight when in contact with the ends of the tubes which they close. These discs are of thin brass, with a thin piece of indiarubber cemented on their under surfaces, and a fine steel wire, about 8in. in length, is fixed to the disc *r*, and passes downwards through a hole in the disc *c*, through which it must slide, with little friction, but air-tight. Each disc, or valve, is prevented from rising too far by pins which pass through guide-holes in their edges. The disc *r* is shown thus arranged; the disc *c* is exactly like it, but smaller.

The stand and lever, and its appendages, by which an up and down motion is imparted to the tube, is sufficiently explained by the sketch.

The outside tube A is filled nearly to the top with mercury, and when the end *d* of the inner tube is free to the air, the mercury will rise to the same level in the tube E F. But suppose the end *d* to be closed by a vacuum tube, to be exhausted, fixed to it, and the tube E F to be raised by raising the lever G. The air between the mercury and the top of the tube E F will be rarefied, and air from the vacuum tube will enter it to restore the equilibrium. But, at the same time that E F is being raised, the valve *r* is closed, because the steel wire is retained slightly by the disc or valve *c*, through which it passes with a certain amount of friction, due to the indiarubber facing; and, for the same reason, the valve *c* is opened. The valves being in those positions, the air is free to rise through the small tube and enter the amplified space in E F, and, at the same time, the mercury rises slightly in E F. When the tube descends, the positions of the valves are reversed, *c* being opened, and *c* closed; and thus the air in E F is discharged through *c*. E F is then raised a second time, when a fresh quantity of air is abstracted from the vacuum tubes to be discharged through the valve *c*, when the tube is depressed (it will, of course, descend by virtue of the atmospheric pressure). The mercury will continue to rise in E F, and sink in A, at every upward stroke, and that till the air is entirely exhausted from the tube, when the mercury will have risen nearly to the valve *c* in E F, and a column, 30in. in length, obtained.

I hope that I have made clear its construction and action, and trust that some of our numerous contributors will give their candid opinions as to whether the scheme is practicable or not. A cheap, simple, and effectual air-pump would, I am sure, be a welcome acquisition to the experimental amateur.

RADIANT MATTER.

[17195.]—ALTHOUGH the beautiful and important researches of Mr. Crookes, in relation to radiant matter, have attracted much attention both here and on the Continent, no attempt, as far as I am aware, has yet been made to apply them to any of the numerous phenomena in physical science which have hitherto eluded philosophical explanation. I allude, especially, to certain celestial phenomena, in which such a highly attenuated form of matter as that existing in the vacuum tubes of Mr. Crookes, appears to me to be intimately concerned—namely, the sun's corona, the zodiacal light, and comets. I wish, however, in these brief remarks, to refer to radiant matter solely in its relations to the latter class of bodies, and to point out a few of the analogies in a physical point of view between it and the vaporous substance of which all comets are found to be composed, and which the spectroscope seems to indicate as some volatile form of carbon. Like this radiant matter, this cometary matter exists, as I have intimated, in a state of extreme tenuity, or, to use the words of Sir John Herschel, it is a vapour or fog, of almost spiritual lightness, as is sufficiently proved by bright stars, such as Arcturus, in the case of Donati's comet of 1858, shining through the brightest part of the tail of that comet, without being in the least dimmed, although the light must have there shown through a thickness of 90,000 miles of this mist.

English Mechanic April 23/1880

Now Sir John was so struck with the peculiar repulsive properties manifested by cometary matter under the influence of the sun, that he hesitated not to call it "levitating," in contra-distinction to "gravitating," or ordinary matter. And in the lecture on "Comets," in his familiar lectures on "Scientific Subjects," from which I have quoted, he speaks of "the phenomena of the tails of comets as affording positive and unrefutable demonstration of the existence in nature of a repulsive force co-extensive with but enormously more powerful than the attractive force we call gravity." This force, however, he affirms, cannot possibly be either electric or magnetic, because "the discrete particles which go to form a comet's tail, could by no possibility (their polar state being implied) be either attracted or repelled by a body, however powerfully magnetised or electrified, placed at the distance of the sun; for, he adds, "the attraction on one side of such a particle would be precisely equal to the repulsion on the other."

If, however, we regard radiant matter, to which in its marvellous tenuity the "levitating" matter of Herschel seems to be so closely allied, we find that it exhibits extreme mobility under the influence of the electric current, and also, as is beautifully shown by the radiometer, under the action of light and heat. In fact, this instrument appears to me to afford a ready explanation of the remarkable phenomenon already referred to,—namely, the powerful repulsive energy evidently exerted by the sun upon the tails of comets, inasmuch as they are invariably thrown out, as is well known, in a direction exactly opposite the sun. For, if the arms of the radiometer are moved by heated molecular currents formed within it, and which thus exhibit considerable repulsive force, we can easily conceive that cometary matter in the neighbourhood of the sun may be so acted upon by its intense heat as to give rise to similar currents, and that the interior of the head of a comet may consequently be propelled outwards, or from the sun so as to form a tail, by the powerful tension or pressure of the highly-heated currents generated upon its exterior surface. This tail we may also conceive as capable of any extension, however vast, being, as it would, under the influence of similar propelling currents from its exterior, while acted upon by the sun. And here, to meet an objection to such a theory, it may be necessary to observe that cometary matter, notwithstanding its extreme tenuity, is, without doubt, under the control of gravity, and that coercive force is so great as a comet approaches the sun, that such matter is wholly prevented from passing away into free space, and is, therefore, *virtually* in the same condition as the radiant matter in the bulb of the radiometer. Or we may perhaps, better express what takes place in the case of the comet, by saying that its matter is acted upon by two forces, a powerful gravitating, and a far more powerful repulsive force, and that the molecules accordingly move in the direction of the resultant of these forces, or backwards when a tail is formed. This repulsive force may, perhaps, likewise account for the retrograde orbital motion of many comets.

Another remarkable characteristic of radiant matter may here be noticed, and which is particularly referred to in the able paper on the subject, from the *Revue des Deux Mondes*, which appeared in your 780th number, namely, "The Motion of Molecules in Right Lines"; the author observing if "they (the molecules in the vacuum tubes) are thus impelled, they ought to exercise mechanical power in the direction of their propagation. Their course is sufficiently long for this effort or pressure not to be transmitted instantaneously in every direction as taking place in gas at the ordinary tension." If, then, upon our hypothesis, radiant and cometary matter are identical in physical properties, we must regard the molecules of the latter as also differing from those of an ordinary gas in not transmitting pressure in every direction but only in that of their propagation; that is, conformably to observation, towards the tail. Thus, independently of the potent action of gravity upon it, cometary matter would have no tendency like a gas to pass away in any other direction into space.

If, too, both these forms of matter are governed by the same laws, it would seem that there is no necessity, from the phenomena of comets, to assume, as in the passage above quoted, Sir John Herschel assumed, the existence of a special all-powerful repulsive force residing in the sun, because the solar heat and light would, I conceive, be adequate to account for them, at least, in a dynamical point of view. There is also every reason to believe that the sun is, too, the centre of most powerful electric and magnetic forces, and these, like the calorific and luminous, would, as in ultra-gaseous or radiant matter, exert a direct influence upon the matter of comets, if both have the same physical constitution.

Another very striking feature in comets—their luminosity—seems also to be very well explained upon the theory which I have ventured to submit; for if, as it assumes, the matter of a comet is in an ultra-gaseous condition like that in a vacuum tube, it must, I repeat, be also in a state of violent intestine or molecular motion under solar energy; in other words, of intense heat, and may become consequently self-luminous or incandescent.

According to Wickmann, luminosity in Geissler tubes "appears far under a 100° cent."

I might refer likewise to the dark space around the negative pole of a vacuum tube in relation to the dark spaces between "the cappings of light" or envelopes formed sometimes in front of the nucleus of a comet, as in Donati's of 1858, but will not further extend my imperfect remarks.

Stoke Newington, April 5th.

Eng Mech March 5 1880

"RADIANT MATTER."*

By Adolphe Wurtz.

EVERYONE knows that matter presents itself to us in different states of aggregation, in solid, liquid, or gaseous conditions.

The gaseous state, in some respects the most subtle of all, has been the most difficult to understand and define, and although common facts of observation, such as the force of the wind, have shown to the Greeks the material nature of the atmosphere, yet the existence of aeriform fluids of different forms has only been recognised in modern times. This discovery is attributed to the Belgian Van Helmont, whose works go back to the first half of the seventeenth century. To him we owe the word "gas." It was he also who first distinguished permanent gases from vapours, a distinction which maintained itself in science for two and a half centuries, and which the recent discoveries of Messrs. Cailletet and Raoul Pictet have only just caused to disappear.

Aerial particles are formed of material particles like liquids and solids themselves, but these particles are placed at such distances that the force of attraction or cohesion has lost the power of aggregating them one to another. In a gas, this cohesion is sensibly nul, its ultimate particles, floating freely in space, being freed from it. They do not float in it in an indifferent manner, but are animated by an unheard-of quickness of movement, submitted to certain laws and producing certain effects. This idea was introduced into science about 1738, by Daniel Bernouilli and developed recently by different savants, at whose head shine Messrs. Clausius and Clerk-Maxwell.

Imagine a certain volume of ordinary air shut up in a closed space, of the form and capacity, for instance, of a cubic centimetre. In this little volume the air, consisting of four-fifths nitrogen, and one-fifth oxygen, contains, according to the ideas just brought forward, innumerable legions of gaseous molecules, moving in right lines with a mean velocity of 485 metres per second. Their number is so immense that every instant they meet, clash together and rebound in all directions, striking everywhere the sides of the containing vessel. The tension of the air, or of any gas, that is the pressure it exerts against the sides of the vessel, is exactly the result of these multiplied shocks—of this molecular bombardment. And such is the rapidity with which these movements take place and are communicated from particle to particle that the pressure exercised is transmitted instantaneously on all sides. The distances passed over freely by the molecules of air between two collisions are extremely short, at the temperature of freezing-point, and under the normal pressure, for, according to the calculation of the most learned scientists, they do not attain the ten-millionth of a millimetre, a distance about twenty-five times less than the smallest magnitude visible under a microscope. But where the pressure diminishes, the number of molecules diminishes in the same proportion, and becoming freer in their movement, can then pass over much larger spaces without colliding; in other words, in a rarefied atmosphere, the molecular paths or distances of free course become longer, and may attain as much as several centimetres when the rarefaction of the air is decreased to the millionth part of an atmosphere. An absolute vacuum does not exist, or at any rate cannot be produced, and in air reduced to the degree of rarity which we have just mentioned there still exist myriads of gaseous molecules passing over in straight lines distance relatively considerable, and endowed for this very reason with new properties recently discovered by Mr. Crookes.

The illustrious inventor of the radiometer, making his own an expression employed by Faraday as early as 1816, has given the name of "radiant matter" to that matter which still exists in those spaces which we have been accustomed to consider as empty, but which are not so in reality. By some brilliant experiments which he made in the month of August last year at the meeting at Sheffield, and which he has just repeated at Paris before the faculty of Medicine, and at the Observatory, with the help of Mr. Salet, Mr. Crookes has established the properties of radiant matter, thus penetrating into a region hitherto completely unknown, making the limits of things that are known touch upon those that we are ignorant of, and which we shall perhaps never understand. In the statement we are about to try to make, we shall be deprived of the aid of the beautiful experiments, by which Mr. Crookes astonished and delighted his audience. We shall endeavour, therefore, to reduce this abridgment to terms so simple that everyone may understand.

When an electric spark leaps between two conductors it furrows the air zigzag-fashion, like a small flash of lightning. We have, now, a tube inclosing very rarefied air, and terminated at its two extremities by two metallic wires hermetically sealed into the glass, and by which an electric discharge may be made to pass. Under these circumstances it is no longer an electric spark that is seen in the tube; the latter becomes wholly illuminated, and the light will be variously coloured, according to the nature of the rarefied atmosphere that the tube incloses. This is what is called a Geissler tube.

For a long time physicists have noticed that around the negative pole there exists a dark space, whilst the rest of the tube is luminous. Now Mr. Crookes has ascertained that this space increases in length in proportion as the air is rarefied, and he has been led to believe that its length represents exactly the length of the free path of the molecules. As those which dart forward, strongly excited, from the negative pole, meet with but few, if any, molecules in the whole extent of the obscure space, no light darts forth; a light only appears when the electrified molecules strike against each other, or against the sides of the tube itself. To this last may be given dimensions such, that after having produced a vacuum of a millionth of an atmosphere, the molecules, almost entirely free from the shocks of their neighbours, dart from the negative pole right to the extremity of the tube, this length representing the distance of free path. This is what is called a Crookes tube.

While the current of electrified molecules cross it, there appears on the sides of the containing vessel a greenish light—chiefly on the side of the negative pole—the glass has become phosphorescent. Under these conditions other bodies become still more luminous than glass. It is especially the case with the sulphide of calcium, whose phosphorescence was discovered twenty years ago by M. Ed. Becquerel. In connection with this, a beautiful experiment is to project the electrified molecules upon a diamond which then emits a greenish yellow light. Ruby shines with a bright red, and as it is made of that white earth called alumium, and which can be precipitated from alum if the electric discharge is sent through a Crookes tube inclosing this aluminium, it also gives out a bright red light.

Radiant matter is propagated in straight lines, like light itself. The electrified molecules separate from the negative pole at a normal to the surface, and if to this pole is given the form of a little concave mirror, the molecules can be concentrated to a focus, beyond which they diverge anew; but when the atmosphere of the tube is very rarefied, no light marks the passage of these novel rays; the sides of the tube opposite the negative pole alone are lit up at the place where the molecules, flying before the pole in a right line, strike the glass. When there is placed in the path of this current of radiant matter a little screen, such as a leaf of aluminium cut into the form of a cross, the shadow of this cross will be projected on the opposite side of the tube, because the molecules, arrested in their rectilinear course, can no longer excite the parts of the glass situated opposite the screen, while the neighbouring parts will continue to be exposed to the molecular shocks, and will be illuminated. But a curious circumstance is that the impression that the glass receives, and which renders it phosphorescent, diminishes in intensity with the duration of the experiment. If, then, the cross is turned round, so as to unmask the parts of the tube on which it projected its shadow, these parts, receiving in turn the molecular shocks, will be illuminated more than the others, which seem already fatigued, and the little cross will stand out luminous from the bottom of the tube.

This torrent of electrified molecules, which are precipitated in right lines from one extremity of the tube to the other, can be made to deviate from their path by the action of a magnet. Mr. Crookes employed an ingenious artifice to make this deviation visible. He arranged one of his tubes so that the molecular stream should just touch a phosphorescent screen placed lengthways, and on which will appear a luminous line; this was visibly bent by the action of a magnet applied at the middle of the tube.

If it is true that they are really material molecules that are thus impelled in a right line, they ought to exercise mechanical power in the direction of their propagation. Their course is sufficiently long for this effort or pressure not to be transmitted instantaneously in every direction, as takes place in gas at the ordinary tension. This is precisely one of the most characteristic properties of radiant matter, and Mr. Crookes has shown it by means of various and ingenious experiments.

In one of his tubes he placed longitudinally little rails, on which he disposed a little wheel, with vanes, so that the stream of molecules of radiant matter could meet the vanes in the upper part of the tube.

At the moment of the discharge, the wheel commences to revolve, and flies before the negative pole, impelled by the molecular current, and it retraces its path immediately the electric current is reversed. Let there now be placed before such a wheel a screen, and on this screen let there be concentrated, by aid of a little concave mirror, forming the negative pole, the currents of radiant matter, in such a manner that they can no longer touch the vanes, and the wheel will rest motionless. But, by the aid of a magnet, turn aside the stream towards the upper part, and the radiant matter will meet the vanes, no longer protected by the screen, and will immediately impress upon the wheel a movement of propulsion.

Mr. Crookes employed the radiometer to complete his beautiful demonstration. Every one has seen the arms of this instrument revolve, like a little windmill, turning backwards in a glass globe, in which the air has been rarefied. It is the direct action of the wind which turns the arms of a windmill. In the radiometer, on the contrary, the arms turn from the effect of a recoil, which is easy to explain. Each of them receives the impression of the calorific rays upon one of its faces, covered by a substance that is absorbent, and susceptible of being heated more than the other. The molecules of air, which rebound after having struck against this warmer face, tend to make the the arm recoil, like the jet of water makes the arm recoil in the hydraulic tourniquet. The arm that seems to fly before the calorific rays turns, in reality, because it is repelled by the molecular current which moves from one of its surfaces. But, for this effect to have place, it is necessary for the atmosphere of the globe to be very rarefied. At the ordinary pressure, the distances of free path are so short, and the molecular collisions are so numerous, that the excess of pressure of the particles that start from the warm face is communicated instantaneously from molecule to molecule, to the entire gaseous mass, and is propagated in all directions, so that the opposite face of the arm receives at the same instant an equal and opposite impulse to that of the warm face. The arm then remains at rest, and the radiometer does not revolve in a gas at the ordinary pressure. This delicate instrument is indeed well-named; after long discussion on the appearances it presents to us, physicists now recognise that they are not the calorique or luminous rays of the ether, but rather the gaseous molecules of the rarefied atmosphere itself, which put it in movement. In other words, it is the radiant matter which is emitted in some manner from the warm face, and which causes it to revolve. It can be put in movement by electrified radiant matter, if, as Mr. Crookes has done, a radiometer is placed so that the metallic faces of the wings form the negative pole, and are placed at a certain distance from the positive pole. When the discharge is passed, different effects are produced, according to the degree of rarefaction of the air.

At a pressure of a few millimetres of mercury, a halo of violet light shows itself on the metallic surfaces of the arms; as the pressure diminishes, the dark space of which we have spoken above makes its appearance before the arm and the light, and recedes in proportion as the rarefaction augments. The rotation commences as soon as it extends towards the borders of the glass, and becomes very rapid when it touches it, a new proof that there exists a correlation between the degree of rarefaction, the extent of dark space, and the properties of the residual gas.

In this electric radiometer the molecules of air which flee from before the negative pole repel the arms because the distances of free path have become sufficiently considerable for the pressure not to be able to be propagated instantaneously in all directions. It is the principle of the ordinary radiometer, with the difference that the gaseous molecules are electrified; in fact, they are in a particular state of excitation, as if a new force were added to that force which the molecular movement represents. It is then necessary to keep in mind the intervention of electricity in these beautiful experiments of Mr. Crookes, and also the influence that it may exercise on the properties of radiant matter.

Among other properties, one of the most curious is relative to the transmission, or, rather, the transformation of the molecular movement, of which we have just spoken. Stopped or deadened, it is converted into heat, and this projection of the electrified molecules sent forward with force against the sides of the tube, determines not only the phenomena of phosphorescence of which we have already spoken, but also a sensible heating of the tube. Mr. Crookes has shown this disengagement of heat by a striking experiment. By the help of a concave mirror, he concentrated a molecular current on a little piece of platinised iridium; this almost infusible metal was at first raised to most active incandescence, and melted when the intensity of the discharge was augmented.

It is the physical properties of radiant matter that we have just made known, and the properties are the same, whatever be the chemical nature of the gas submitted to experiment. At a low pressure, hydrogen, carbonic acid, or atmospheric air, show the same phenomena of phosphorescence, of magnetic deviation, of heating; only that these phenomena commence at different pressures. But, curiously, in this state of extreme tenuity, when radiant matter seems to take upon itself some of the properties of the ether, or of radiant energy, the molecules yet preserve their individuality, and their peculiar character: carbonic acid continues to be absorbed by potash, the vapour of water by phosphoric anhydride, hydrogen by the metal palladium, and oxygen by carbon, which it burns. The permanence of these chemical properties has been made use of to carry the rarefaction of the gas to a degree unknown till now. Thus in tubes in which the air has been reduced an excessively feeble pressure, this air can be replaced by water vapour, and this may be absorbed in its turn by a substance absorbent of water, such as dry potash, or phosphoric acid. It is by employing means of this kind, that Mr. Crookes has been able to produce a vacuum which he reckons at the twenty-millionth part of an atmosphere.

But is it true that the effects of which we have spoken are due to a projection of molecules, and could not the electric discharge itself produce them? The eminent physicist has himself foreseen this objection, and has answered it. It is known that two bodies charged with the same electricity repel each other, whilst two currents of the electric fluid attract when they are propagated in the same direction, as our immortal Ampère has shown. Now Mr. Crookes has shown that two currents of radiant matter which are propagated in the same tube and in the same direction are mutually repelled; they are, therefore, formed by a transport of electrified matter, and one repels the other because they are of the same name. It is known also that in spaces where the vacuum is carried to the extreme degree we have mentioned, the electric spark refuses to pass, so much is it true that electricity, under all its forms, is allied to matter. We may say of it with more reason what Goethe said of light, "it is engendered by matter, and with matter it will perish."

But, is it possible to admit that these tubes, exhausted to the millionth of an atmosphere, yet inclose so many particles? Yes; they contain a number so prodigious that the imagination stands confounded.

By the help of considerations drawn from the theory of gases that we have explained at the beginning of this study, this number can be calculated. It has been—very approximately, without doubt—for in calculations of this sort, it is always necessary to make use of certain hypothetical data.

According to the most competent authorities on this matter, a bulb of glass of a diameter of ·135 metres incloses more than septilion of molecule! A septilion! This is a million multiplied three times by itself; it is unity followed by twenty-four noughts; and if you divide this quantity by a million, the quotient will represent the number of molecules of air contained in the bulb in question after the air has been rarefied to the millionth of an atmosphere. This quotient is a quintilion; that is to say, a million multiplied three times by itself, unity followed by eighteen noughts. Was I not right in speaking above of innumerable legions of molecules, and has not the mind some trouble to conceive such immensities, as well as to figure the unheard-of smallness of material molecules?

A final experiment of Mr. Crook's brings to the light all the difficulty, but all the grandeur also, of his conceptions. Here is the same bulb we have just been considering; it is exhausted to a millionth of an atmosphere. By means of a powerful spark we can pierce the side, and the opening thus made is so small that to perceive it the eye must be armed with a strong lens. But through this imperceptible opening the exterior air in going to rush into the bulb, and if we suppose (a supposition much under the reality, and which is here made only to give an idea of these immensities) that in a second there could enter a hundred million molecules, do you known how long a time it would take for this little bulb to fill entirely with air at the ordinary tension? Would it be an hour, a day, a year, an age? No; it would be almost an eternity; and supposing the experiment had commenced at the time when our solar system was constituted, it would not be finished when the sun, the abundant but not inexhaustible source of heat, light, and force, should have cooled down and become extinct. These thoughts and these words are those of Mr. Crookes. I desire to leave the reader under their impression.

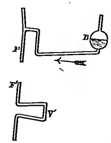
Aug 7 1880

By Professor O. N. Rood, of Columbia College.

In this notice I propose to indicate very briefly the nature of an improvement that I have lately made in the form of the Sprengel pump, which enables the experimenter easily to obtain a vacuum as high as [illegible] or [illegible], reserving the details of manipulation, etc., for more extended notice hereafter.

(1.) The improvement consists, first, in an arrangement by means of which the mercury, instead of being at once introduced into the pump, passes beforehand through an exhausted bulb, B, thus freeing itself in great measure from air and moisture. It afterwards passes through a nearly horizontal tube, finally reaching the fall tube, F, as shown in the diagram.

(2.) The second part consists of what amounts to an almost theoretically perfect fluid valve, which prevents the



air that has passed out of the fall tube from returning into it; this is accomplished by merely bending the fall tube as indicated at V. As for the rest, the pump is contrived so as to be free from stop cocks and grease.

By inclining the pump somewhat, the bulb can be exhausted once for all, as matters can easily be arranged so that when the atmosphere is allowed to enter the pump, the exhaustion of the bulb remains intact.

The action of this pump is very rapid, two hours or less sufficing to reduce the vacuum from [illegible] to [illegible], the total capacity of the pump being 100 cubic centimeters.

The exhaustion in these experiments was always accomplished by mechanical, not by chemical means; chemical substances being introduced solely for the purpose of drying the air. In the total absence of all such substances I have obtained a vacuum as high as [illegible]. The means of measuring these vacua and other details will be given as soon as a set of experiments that are being made on the [illegible]er of the fall tube is finished.—*Am. Jour. of Science.*

THE TELEPHONIC CENTRAL OFFICE SYSTEM.

It is difficult to conceive of an invention more marvelous than that which enables persons to converse with each other without regard to the space that separates them; and it is not only wonderful, but deeply interesting to the student of science, as it involves several of the most prominent physical discoveries of modern times. It is a monument of persevering and difficult study and experiment. From being a mere scientific curiosity, universally believed to be of no practical value, it has now become an important factor in the daily business and social life of this and other large cities.

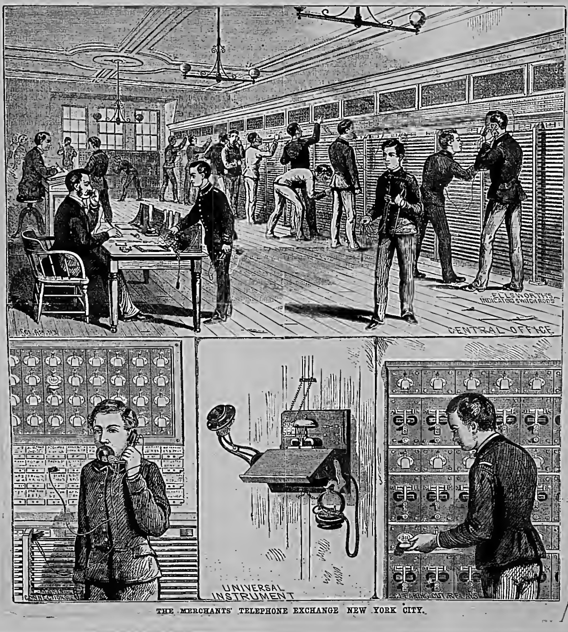
The uses to which the telephone is already applied, its future and its possible applications, will be considered in another place, the object of the present article being to afford the general reader an idea of the details of the arrangement and working of the central office system, which increases the usefulness of the telephone manyfold.

We have chosen for illustration as an example of this system in its perfected form, the Merchants' Telephone Exchange, located at 198 Broadway, and controlled by the Gold and Stock Telegraph Company of this city.

The telephone shown in the lower central figure in the accompanying engraving scarcely needs description, its construction and the details of its operation having been repeatedly described in these columns. In brief, the adjustable arm carries an Edison carbon button transmitter, connected with the primary wire of an induction coil concealed beneath the desk. A receiving telephone, which is connected with the line wire, hangs upon a switch at the opposite end of the desk. Removing and replacing the telephone operates the switch. Above the desk there is an ordinary single-stroke electric bell, and below it are two cells of Leclanché battery.

This telephone is one of many, each of which is connected by a single wire with the central office, the interior of which

[*Continued on page 2[illegible].]



THE MERCHANTS' TELEPHONE EXCHANGE NEW YORK CITY.

2

THE TELEPHONE CENTRAL OFFICE SYSTEM.

[*Continued from first page.*]

is represented in the larger view in the engraving. Each person having the use of a telephone connected with the central office is called a subscriber, and his wire entering the office is connected with a small switch—a jack-knife switch; just below his name, and by this switch an electrical communication between the line and one of the annunciators above the switch is established or broken.

The arrangement of a telephone line in its normal condition is as follows: One wire from the subscriber's local battery is grounded; the other connects with the push button seen at the side of the desk. When this button is pressed the current from the local battery passes through the line wire, through the switch at the central office, through the magnet of the annunciator to the ground. The effect of the passage of the current through the annunciator is to release the little cover concealing the number of the subscriber's wire, permitting it to drop and expose the number. On seeing the number, the switchman connects his portable telephone with the subscriber's line, by inserting the plug at the end of the flexible telephone cord in the jack-knife switch. This operation not only connects the switchman with the line, but it also breaks the connection between the subscriber's line and the annunciator. The switchman's telephone being already connected with a battery and induction coil, and in condition to talk over the subscriber's line, he says to the subscriber, whom we will call A: "Well, A; what will you have?" A then says: "Connect me with B (say) at 25 Wall street."

The switchman then connects A's jack-knife switch with one of the long horizontal bars seen below; switches and turns the bar slightly, to indicate that it is occupied. He then goes to B's jack-knife switch; inserts one end of a flexible cord in the switch, and taps on a long brass strip connected with the central office battery, thus sending electrical impulses through B's line wire, ringing B's bell, when B removes his receiving telephone from its switch, and listens while the switchman connects B's jack-knife switch with the same horizontal rod that is connected with A. He then removes A's connection from the rod, and tells A "All right; go ahead," when the conversation between A and B proceeds. It takes only seconds to do what has required minutes to describe.

The boys attending the switches become expert and rarely make mistakes, although it is difficult to see how anything could be done correctly amid the din and clamor of twenty or thirty strong voices crying, "Hello! hel-l-o, A!" "Hello, B!" "What will you have?" "Who?" "Which?" "What?" "A-l-l right," and so on. It seems anything but orderly and systematic; but, nevertheless, it is the very embodiment of order and system. There are no less than six thousand calls per day; yet there is no delay, no mistakes, no trouble, save from the occasional breaking of a wire or the crossing and interference of one wire with another.

An idea of the activity of a telephone central office may be obtained from the larger view. The actual condition of things is far from being exaggerated.

It doubtless will be asked, How is it known at the central office when A and B have finished talking? The clearing out relays shown in one of the lower views, and at the farther end of the office in the upper view, indicate this. These relays, which are of comparatively high resistance, are each arranged to work a local circuit in which there is an annunciator representing one of the switch rods.

Each horizontal switch rod is connected with one of the relays, and all of the relays are grounded. Now A, having begun the conversation through the telephone, must indicate when it is ended; therefore, upon hanging up his receiving telephone, he pushes the button four or five times, working the relay, and consequently the annunciator connected with it, indicating that whatever is connected with the horizontal switch rod whose number corresponds with that of the annunciator, may be removed, and the switch rod may be used for C and D, or any one else.

One desk, seen at the right of the larger engraving, is the chief operator's desk, and the line-men, whose business it is to rectify troubles, get their orders at this desk.

There are upwards of 800 wires entering this office alone, and it requires over a thousand cells of battery to work this maze of wires.

Persons desiring to avail themselves of this means of communication subscribe to certain conditions, which require, among other things, the payment of a monthly rental, and the observance of the rules of the company. Men are then sent from the central office to place the telephone and battery, and to run from the subscriber's telephone to the central office a wire, supporting it at intervals by poles and fixtures as in the case of telegraph lines. The line and the instrument are kept in order by the company. Any imperfection in the action of either reported to the chief operator's desk at the central office receives immediate attention, men being sent out at once to find and remedy the trouble.

An alphabetically arranged list of subscribers is furnished with each telephone, and as new subscriptions are made, supplementary lists are furnished to all subscribers.

Among the recent improvements in telephone exchanges is the portable switchman's telephone, which is clearly shown in the lower left-hand view in the engraving, and the switch rods, shown in the same view, and also in the larger one. The latter are the invention of Mr. T. G. Ellsworth, the manager of the central office. They certainly save a great amount of labor, and prevent confusion and trouble.

The telephone, like many other modern inventions, needs to be used to be appreciated. It is wonderful enough that we are enabled to talk to persons in all parts of this great city, but when we can talk without difficulty with persons in neighboring cities, it becomes even more wonderful and interesting. The lines which connect New York with Newark run under the North River. Those that connect New York and Brooklyn are suspended from the East River bridge towers. The wires may run underground, under water, or high in air.

The large and rapidly-increasing number of telephone lines indicate the growing popularity of this means of communication, and we confidently expect at no distant day to see it almost universally adopted for business and even domestic purposes. Already the wires extend in every possible direction from the central office, and fairly darken the sky in some localities. The Gold and Stock Telegraph Company have in this city three exchanges similar to the one we have described, connected with each other, and, with the central office systems, several of the adjoining cities. Jersey City, Newark, and Orange, N. J., and Brooklyn, N. Y., are so connected. Yonkers, and, in fact, all of the other important cities surrounding New York, will undoubtedly be telephonically connected with the metropolis before the beginning of another year. We understand New York and Philadelphia are soon to be connected in this way. The convenience of such means of communication is thoroughly appreciated by business men, whose operations are confined to a few hours, and whose time is valuable. The SCIENTIFIC AMERICAN has constant proof of the utility of this invention, as there is scarcely an hour in the day that the telephone in the office is not used in communicating with some one, either in this or one of the adjacent cities.

The operation of this telephone will be understood by those who are familiar with the first electro-chemical telephone. The vibration of the diaphragm of the transmitting instrument varies the contact between the carbon and the two electrodes, so that a varying current is sent through the primary of the induction coil; this of course produces a secondary current of varying intensity in the secondary wire of the induction coil, which being in circuit with the secondary wire of the induction coil of a distant instrument produces a current in the tertiary wire wound around the secondary coil. The tertiary current passes through the chalk cylinder and the platinum-faced rubber, and as the chalk cylinder revolves, the friction of the rubber is varied according to the variation of the primary, secondary, and tertiary currents. The platinum-faced rubber is connected with the diaphragm, and the friction of the rubber is sufficient, when no current passes, to pull the diaphragm forward as the cylinder is turned; but when the slightest current is sent through the primary coil, the induced tertiary current transforms the frictional surface of the chalk into a frictionless surface and the diaphragm springs back. All this describes a single vibration of the diaphragm, thousands of which are required for the utterance of a single sentence. It is not essential that the current should be broken to produce the effect in the receiver. It is probable that an absolute break never occurs in the ordinary use of the telephone.

An ordinary call bell is adopted in this system as a means of giving an alarm.

This telephone is unrivalled for loudness of speech, and an electro-magnet is not required in its construction.—*Scientific American.*

THE LONTIN ELECTRIC LIGHT ON THE METROPOLITAN RAILWAY.

ON Monday evening, the 6th inst., at the invitation of Mr. Myles Fenton, General Manager of the Metropolitan Railway, a number of the representatives of the metropolitan press were present at the Aldersgate Street station of the Metropolitan Railway, to witness some experiments with the Lontin Electric Light. The system of Electric Lighting has been carried out by the *Electric Generator and Light Company*. The generator is that known as the "Lontin." The principal advantages claimed for this machine being, "The low speed at which it works," "The ready division of the light," and "The production of alternate currents."

The Lontin machine works at a maximum speed of 400 revolutions, whereas those hitherto employed in public lighting are worked at from double to treble that rate. The great advantages of low speed are the enormous reduction of wear and tear, of risk of accident and of over-heating.

The light may be very much sub-divided. As many as 12 lights have been placed on one circuit. It has been shown practically that by the machine it is possible to give a larger number of small lights, and, so far as experience has hitherto gone, whatever loss there may be in illuminating power is much more than compensated for by the convenience of

Cosmopolitan Jan. 1881.

CINCINNATI electricians have succeeded in solving a most difficult question. By a new invention a circuit automatic repeating system for the transmission of messages to any distance has been provided. By its means, as ascertained by experiments carried on in New York and Philadelphia, the vibrations of the articulate human voice can be conveyed from New York to San Francisco with the same ease with which they are conveyed from one part of a city to another.

The Blake Transmitter.

To the Editor of the Scientific American:

3

It is somewhat remarkable that the friends and admirers of Mr. Edison take such great pains to prove to the world that he is the inventor of every electrical instrument and contrivance which turns out to be of value.

Not satisfied with the signal defeat which Mr. Edison sustained in the great microphone controversy in Europe, where the leading scientists, without exception, supported the claim of Professor Hughes, that the microphonic action is totally different from the principle which Mr. Edison has always claimed as the basis of his carbon telephone, viz., "the property possessed by some substances of moderate conductivity of having this power modified by pressure," although even this cannot be regarded as his exclusive property, as it was discovered as early as 1856 by the Count Du Moncel, and described by him in his "Exposé des Applications de l'Electricité," and also used by M. Clerac in 1865—not satisfied with this, I repeat, an attempt is now made to induce the public to believe that Mr. Edison is also the inventor of the only really successful microphonic transmitter ever produced. I allude to that invented by Mr. Francis Blake, of Newton Lower Falls, Mass., and described in your issue under the date of November 1.

Wherein the similarity between the Blake and the Edison transmitters lies, it is difficult for one acquainted with both to say, save in the fact that both are used in combination with an induction coil, the secondary circuit of which is a part of the main line.

I have examined Mr. Prescott's account of Mr. Edison's inertia telephone, and find it totally different, both in action and principle, from any microphone.

It appears, however, from the article in question that Mr. Edison's latest transmitter, described also in the SCIENTIFIC AMERICAN a few weeks since, is also like the "old invention," in principle. If so, it is a query why the Western Union Company did not bring out this superior instrument instead of the carbon telephone, when the latter was beaten everywhere by the Blake transmitter. The fact really is that the Western Union tried to imitate the Blake transmitter at different times since its introduction, a year since, and could never make the imitations work, simply because the Blake transmitter has a few technical points on which its success depends, and which are only known to the electricians of the National Bell Telephone Company.

Mr. Prescott states in his book, and it is found to be true in practice, that although many substances may be used as a conducting medium for varying resistances in the Edison transmitter, lampblack is the best; per contra, lampblack is not used in the Blake transmitter at all, the substance used being invariably very hard gas carbon, besides which Mr. Edison himself states in his patent 203,016, that unmixed carbon is not adapted for use in his transmitter.

The article we have alluded to as in your last issue, in its second paragraph states that there is "nothing delicate or fine about the construction" of the Blake transmitter. In the third paragraph we find the words, "this casting supports two delicate springs, etc." One of the main features in this transmitter is the delicacy of the adjustment obtained by means of the casting, which is perpendicularly across the inside of the diaphragm, and the screw in its lower end. In conclusion, I desire to say that no cavilling spirit dictates these remarks, but simply a desire for justice to the Blake transmitter, its inventor, and perfecters.

Boston, October 29, 1879. T. D. LOCKWOOD.

THE TELEPHONE CENTRAL OFFICE SYSTEM.

[*Continued from first page.*]

is represented in the larger view in the engraving. Each person having the use of a telephone connected with the central office is called a subscriber, and his wire entering the office is connected with a small switch—a jack-knife switch; just below his name, and by this switch an electrical communication between the line and one of the annunciators above the switch is established or broken.

The arrangement of a telephone line in its normal condition is as follows: One wire from the subscriber's local battery is grounded; the other connects with the push button seen at the side of the desk. When this button is pressed the current from the local battery passes through the line wire, through the switch at the central office, through the magnet of the annunciator to the ground. The effect of the passage of the current through the annunciator is to release the little cover concealing the number of the subscriber's wire, permitting it to drop and expose the number. On seeing the number, the switchman connects his portable telephone with the subscriber's line, by inserting the plug at the end of the flexible telephone cord in the jack-knife switch. This operation not only connects the switchman with the line, but it also breaks the connection between the subscriber's line and the annunciator. The switchman's telephone being already connected with a battery and induction coil, and in condition to talk over the subscriber's line, he says to the subscriber, whom we will call A: "Well, A; what will you have?" A then says: "Connect me with B (say) at 25 Wall street."

The switchman then connects A's jack-knife switch with one of the long horizontal bars seen below; switches and turns the bar slightly, to indicate that it is occupied. He then goes to B's jack-knife switch; inserts one end of a flexible cord in the switch, and taps on a long brass strip connected with the central office battery, thus sending electrical impulses through B's line wire, ringing B's bell, when B removes his receiving telephone from its switch, and listens while the switchman connects B's jack-knife switch with the same horizontal rod that is connected with A. He then removes A's connection from the rod, and tells A "All right; go ahead," when the conversation between A and B proceeds. It takes only seconds to do what has required minutes to describe.

The boys attending the switches become expert and rarely make mistakes, although it is difficult to see how anything could be done correctly amid the din and clamor of twenty or thirty strong voices crying, "Hello! hel-l-o, A!" "Hello, B!" "What will you have?" "Who?" "Which?" "What?" "A-l-l right," and so on. It seems anything but orderly and systematic; but, nevertheless, it is the very embodiment of order and system. There are no less than six thousand calls per day; yet there is no delay, no mistakes, no trouble, save from the occasional breaking of a wire or the crossing and interference of one wire with another.

An idea of the activity of a telephone central office may be obtained from the larger view. The actual condition of things is far from being exaggerated.

It doubtless will be asked, How is it known at the central office when A and B have finished talking? The clearing out relays shown in one of the lower views, and at the farther end of the office in the upper view, indicate this. These relays, which are of comparatively high resistance, are each arranged to work a local circuit in which there is an annunciator representing one of the switch rods.

Each horizontal switch rod is connected with one of the relays, and all of the relays are grounded. Now A, having begun the conversation through the telephone, must indicate when it is ended; therefore, upon hanging up his receiving telephone, he pushes the button four or five times, working the relay, and consequently the annunciator connected with it, indicating that whatever is connected with the horizontal switch rod whose number corresponds with that of the annunciator, may be removed, and the switch rod may be used for C and D, or any one else.

One desk, seen at the right of the larger engraving, is the chief operator's desk, and the line-men, whose business it is to rectify troubles, get their orders at this desk.

There are upwards of 600 wires entering this office alone, and it requires over a thousand cells of battery to work this maze of wires.

Persons desiring to avail themselves of this means of communication subscribe to certain conditions, which require, among other things, the payment of a monthly rental, and the observance of the rules of the company. Men are then sent from the central office to place the telephone and battery, and to run from the subscriber's telephone to the central office a wire, supporting it at intervals by poles and fixtures as in the case of telegraph lines. The line and the instrument are kept in order by the company. Any imperfection in the action of either reported to the chief operator's desk at the central office receives immediate attention, men being sent out at once to find and remedy the trouble.

An alphabetically arranged list of subscribers is furnished with each telephone, and as new subscriptions are made, supplementary lists are furnished to all subscribers.

Among the recent improvements in telephone exchanges is the portable switchman's telephone, which is clearly shown in the lower left-hand view in the engraving, and the switch rods, shown in the same view, and also in the larger one. The latter are the invention of Mr. T. G. Ellsworth, the manager of the central office. They certainly save a great amount of labor, and prevent confusion and trouble.

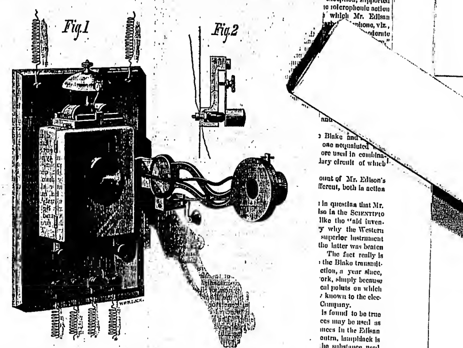
The SCIENTIFIC AMERICAN has constant proof of the utility of this invention, as there is scarcely an hour in the day that the telephone in the office is not used in communicating with some one, either in this or one of the adjacent cities.

3

of Professor Edison's earliest and best telephones or microphones. It is exceedingly simple and does not require frequent adjustment, while it is equally as sensitive as existing forms of transmitter. The details of its construction will be understood by fig. 2. A vulcanite arm is secured to the centre of the mica diaphragm by means of a small bolt, which is connected with one pole of the battery by a piece of metallic foil or very thin copper wire. The head



of this bolt is platinum-faced, and sunk deeply in the vulcanite arm, the same cavity containing also a piece of carbon pencil, such as is used for electric candles. The carbon fits the cavity loosely and is rounded at both ends. Its outer end is pressed by a platinum-faced spring secured to the outer end of the vulcanite arm. The spring carries at its free end, exactly opposite the piece of carbon, a brass weight, and the pressure of the spring upon the carbon is regulated by the small set screw. A wire or piece of copper foil, connecting with the spring, completes an electrical circuit, which includes the primary of an induction coil contained by the rectangular box. The secondary wire of the induction coil is connected with the telephonic line, and a tertiary coil which envelopes the secondary is connected with the rubber, and chalk cylinder of the receiving instrument. Below the transmitter box are two keys, the right hand one being used for signalling, the left hand one for completing the tertiary circuit when a message is received.

The cylinder of the receiving instrument is made of precipitated chalk solidified by great pressure. The fluid now used to saturate the chalk is a dilute solution of hydrogen disodic phosphate. Professor Edison has found by a long series of experiments that the solution employed must be that of an alkali or the phosphate of an alkali, and the hydrogen disodic phosphate is found to be superior to all others.

RESEARCHES ON TELEPHONE VIBRATIONS

Nature Dec 25 187

DR. RUDOLPH KONIG, the well-known constructor of acoustical apparatus, has recently brought before the Physical Society of Paris a research of the highest interest, upon the difference of phase which exists between the vibrations of a transmitting and a receiving telephone. In a paper published more than two years ago, Prof. du Bois-Reymond discussed the conditions which determine the intensity and the phase of different sounds transmitted telephonically; and from theoretical considerations deduced the conclusion that sounds of low pitch suffered greater loss by transmission than shrill ones, and that every simple vibration was retarded in phase by a quarter of an undulation. The former of these actions would produce an alteration in the timbre of the voice as received at the end of the line: the latter effect would remain unappreciated by the ear, since the retardation of phase was the same for waves of all periods. More recently Helmholtz has attacked the question in a paper in the *Annalen* of Wiedemann ("Telephon und Klangfarbe"), and, with a theoretical treatment of the question based upon somewhat deeper analysis, has deduced the results that all sounds are weakened by transmission in almost a constant proportion irrespective of their pitch, and that the difference of phase between the vibrations of transmitter and receiver are very small. Dr. König has endeavoured to put these conflicting speculations to the test of experiment, and with marked success.

It may be well, perhaps, to indicate the elementary considerations which led du Bois-Reymond to predict the existence of this hitherto unobserved difference of phase. The currents by which sounds are carried from the transmitter to the receiver in the Bell telephone are induction currents, excited in a coil of insulated wire by the vibrations of the iron diaphragm in front of the permanent magnet which serves as a core. The intensity of these induced currents is greatest when the vibrating diaphragm is moving with the greatest velocity. But the maximum *velocity* of the diaphragm does not occur at the moment when the *displacement* of the diaphragm is greatest. To non-mathematical readers this fact may be explained by reference to the movements executed by a simple pendulum. As the pendulum swings backwards and forwards the "bob" comes absolutely to rest at the moment when its displacement to one side or the other is the greatest, and it moves with the greatest velocity when it passes through the "point of rest" mid-way between its two extreme positions. Mathematically, the matter is equally simply stated. The displacement of a body executing a simple harmonic motion is determined by an equation of the form $u = a \cos \frac{2\pi t}{T}$, where the values of u pass through a regular series of maximum and minimum values as t increases. These successive values are geometrically represented by the heights of the ordinates of the well-known harmonic curve or *sinusoid*, the distances along the horizontal axis O x being proportional to the times. Thus the telephone diaphragm originally at rest begins to move towards the magnet under the influence of the voice. The displacement, which at the origin is nothing, increases until at A it becomes a maximum. Owing to its elasticity the diaphragm flies back, and passing rapidly through its point of starting suffers a displacement in an opposite sense. These movements are graphically represented on the harmonic

curve by the passage of the curve across the axis at B to its minimum or greatest negative displacement at C, the curve recurring from the point D. Now the equation which represents the *velocity* of the moving point will be obtained from the equation of the displacement by differentiating with respect to time. This gives us an equation of the form—

$$\dot{u} = -\frac{2a\pi}{T} \sin \frac{2\pi t}{T} = \frac{2a\pi}{T} \cos\left(\frac{2\pi t}{T} + \frac{\pi}{2}\right),$$

which is, neglecting the constant coefficient of amplitude, geometrically represented by another harmonic curve of identical form, but shifted on so that it begins at a point *a*, or a quarter of the length of the curve O O from the origin. In this second curve the heights of the ordinates represent the varying velocities of the diaphragm, the velocity being nothing at *a* when the displacement at A is a maximum, and being at a maximum at *b* when the diaphragm in flying back passes through its point of rest or has no displacement. Now of these two curves the former corresponds in phase to the movement of the diaphragm of the transmitting telephone, while the second curve corresponds to the variations of velocity, and therefore of the current transmitted, and consequently also corresponds to the motions of the diaphragm of the receiving telephone. Hence it is easy to understand that there exists a difference of phase of one-quarter of an undulation between the movements of the diaphragms of the transmitting and receiving telephones, which will be either a retardation or an apparent acceleration of phase according to the sense in which the transmitted currents traverse the coil of the receiving telephone. These considerations apply only to the telephone of Bell or its modification by Gower, in which the vibrations of the transmitting diaphragm generate the current. They do not apply to the transmitters of Edison and Hughes, which merely regulate the current. In these instruments the strength of the current is proportional to the *displacement*, not to the *velocity*; hence there is no retardation of phase.

The memoir of Helmholtz, which, by introducing certain considerations respecting the mutual inductive actions exercised upon one another by the individual turns of wire in the coil of the telephone, arrived at a somewhat different conclusion, and was principally devoted to the question of the timbre of the transmitted sounds. The previous researches in physiological acoustics of this distinguished physicist had shown that differences of phase affecting individual tones of a compound "clang" do not produce any effect which the ear can detect. This important law the present writer has, however, shown elsewhere to be true only when one ear receives the sound, and to hold no longer in the case of binaural hearing. The equations of Helmholtz indicated the unexpected result that the difference of phase between the vibrations of transmitter and receiver was a quantity so small that practically it might be altogether disregarded, and he arrived at the conclusion that all sounds were transmitted by the telephone with an equal proportionate degree of intensity independent of their pitch, and therefore with unaltered timbre. Here again, however, the writer of this article has shown that the relation between the thickness and diameter of the vibrating diaphragm affects the distribution of the magnetism induced in it by the magnet, as to whether it is lamellar or radial in character, and that this distribution has influence on the timbre of the sound emitted by the receiving telephone, the notes of higher pitch being better given by the disk in whose magnetisation the lamellar distribution preponderates, while the lower ones are better given with a preponderating radial magnetisation. The whole question of timbre of the emitted sounds requires further careful study.

The experiments which M. König has executed entirely confirm the *à priori* reasoning of du Bois-Reymond as to the existence of a difference of phase. Instead of using two vibrating diaphragms, Dr. König takes two tuning-forks accurately tuned to unison, each of them being placed in front of the magnet of a telephone whose disk has been removed, and which are united in the usual manner by wires. The first of the forks being set into vibration with a violin-bow, the second immediately begins to vibrate. The phase of each of the forks is next observed. This has been done in several ways: firstly, by direct comparison of each fork in turn with the vibration-microscope; secondly, by applying the well-known optical method of Lissajous, compounding together the two vibrations rectangularly by throwing a ray of light on to small mirrors attached to the two forks, and reflected from one to the other and then on to a screen. The figure thus produced exhibited unmistakably a difference of phase of an exact quarter of an undulation. A further experiment on compound tones was made with the same general arrangements; two forks, differing by three octaves, being made to take up, one as transmitter the other as receiver, sounds whose higher vibrations were eight times as rapid as the fundamental tone. Here again the difference of phase experimentally found for the higher tone was one quarter of a vibration.

Incidentally two very important facts have been observed by Dr. König. In experimenting he found that a tuning-fork, vibrating in front of the magnet of a telephone *whose circuit is closed*, comes to rest in a much shorter time than the same fork vibrating freely away from the telephone; also that this weakening of the sound is greater in proportion as the distance of the fork from the pole of the magnet is smaller, and also is greater for small amplitudes of vibration than for large ones. These results are not without interest in their bearing upon Mr. Edison's recent attempt to construct a dynamo-electric machine, in which the moving parts should be attached to a large vibrating tuning-fork instead of to a rotating axis. Doubtless the inventor's idea was to get rid of the friction accompanying rotation; for, as the vibrations of the tuning-fork are very nearly simple harmonic motions, and as the simple harmonic motion is the only type which can be propagated without loss by friction through a body, the motions of whose parts are coincident in phase, it might be anticipated that there would be less waste of energy in a "harmonic" engine than in a rotatory one. The important fact however remained behind that by far the greatest part of the work of driving a dynamo-electric machine was not spent in overcoming friction, but in doing the work of moving closed conductors across a magnetic field, a work which, to produce an equal amount of current, requires equal power, whether the motion be one of rotation or of "harmonic" vibration. Many years ago Foucault demonstrated the reality of this resistance to motion by spinning his gyroscope between the poles of an electromagnet; and with a Gramme machine, and also with a Holtz machine, the increased effort necessary to sustain rotation when work is being done is a familiar fact. Dr. König has now demonstrated the existence of a similar phenomenon in the case of the vibrations of the tuning-fork, which comes much sooner to rest when it is doing electrical work than when it is doing no work.

SILVANUS P. THOMPSON

THE WONDERFUL PHONOGRAPH.

A Pleasant Exhibition at the Boys' High School by J. J. Sprenger.

J. J. Sprenger, formerly of this city, who has recently returned from Europe, after having delivered about two hundred and forty lectures on Edison's latest improved phonograph, in connection with exhibitions of the machine itself, gave a very satisfactory exhibition of this marvellous instrument at the Boys' High School shortly before noon to-day. The machine is erected on a stand with a gearing which works with a weight, causing the cylinder to revolve with precisely the same motion when the sounds are reproduced as when they are placed upon the foil. Mr. Sprenger prefaced his entertainment by asking the boys to excuse any murdering of the King's English in his explanations, as he had been lecturing in German so long he had gotten out of practice in the English tongue. He then started the instrument and sang into it, "Home Again, from a Foreign Shore," which tones were reproduced much the same as the singer's natural voice. One of the pupils sang, "Mary had a little Lamb," and the machine also sang it in return. A number of other exercises were gone through with, and the machine did not fail to do its part.

The entertainment was closed by Mr. Sprenger placing upon the machine a cylinder which he had brought from Berlin, which contained a trumpet solo—"Up Comrades, to Horse," and a German song, "On the Green Strand of the Spree," which were very sweetly turned out by the machine.

During the entertainment Mr. Sprenger fully explained the mechanical operations and the scientific principles of the instrument, and he was heartily applauded by the boys at the close.

PHYSICAL SOCIETY, LONDON.

"On Some Physical Points Connected with the Telephone." By Mr. W. H. PREECE.—This instrument may be employed both as a source of a new kind of current and as the detector of currents which are incapable of influencing the galvanometer. It shows that the form and duration of Faraday's magneto-electric currents are dependent on the rate and duration of motion of the lines of force producing them, and that the currents produced by the alteration of a magnetic field vary in strength with the rate of alteration of that field; and further, that the infinitely small and possibly only molecular movement of the iron plate is sufficient to occasion the requisite motion of the lines of force. He pointed out that the telephone explodes the notion that iron takes time to be magnetized and de-magnetized. Mr. R. S. Brough has calculated that the strongest current employed in a telephone is [illegible]th of the CGS unit. Mr. Preece explained that the dimensions of the coil and plate depend on the strength of the magnet, but the former should always consist of fine wire and be made as flat and thin as possible. The adjustment of the position of the magnet (as near as possible to the plate without touching) is easily effected by sounding a vowel sound *ah* or *o* clearly and loudly; a jar is heard when they are too near together. After briefly enumerating the attempts which have been made to improve the instrument, he mentioned the various purposes to which it can be applied. In addition to being useful in the lecture room in conjunction with several well-known forms of apparatus, it forms an excellent detector in a Wheatstone bridge for testing short lengths of wire, and condensers can be adjusted by its means with great accuracy. M. Niaudet has shown, by employing a doubly wound coil, that it can be used to detect currents from doubtful sources of electricity, and it is excellent as a means of testing leaky insulators. Among the facts already proved by the telephone may be mentioned the existence of currents due to induction in wires contiguous to wires carrying currents, even when these are near each other for only a short distance. Mr. Preece finds that if the telephone wire be inclosed in a conducting sheath which is in connection with the earth, all effects of electric induction are avoided; and, further, if the sheath be of iron, magnetic induction also is avoided, and the telephone acts perfectly. A great number of experiments on the use of the instrument on telegraphic lines were then described, from which it appears that conversation can be carried on through 100 miles of submarine cable or 200 miles of a single wire without difficulty with the instrument as now constructed. The leakage occurring on pole-lines is fatal to its use in wet weather for distances beyond five miles. An interesting series of telephones was exhibited, and by means of one of very large dimensions Mr. Preece showed that the current produced by pressing the center of the plate sensibly affects a Thomson galvanometer, and that the motion of the needle ceases in a remarkably instantaneous manner as soon as the pressure is removed, a necessary condition in order that the receiving-plate should accurately reproduce the motions of the sending-plate.

In the discussion which followed—

Mr. R. Sabine suggested that the failure of all attempts at improving the instrument by increasing its dimensions might be due to the *damping* action of the permanent magnet on the plate, the strain on it being proportional to the size of magnet, and rendering it less sensitive to the sonorous waves.

Mr. Collin pointed out how interesting it would be if, instead of employing a receiving instrument, the currents could be communicated directly to the auditory nerves.

Prof. Adams explained the relation subsisting between the character of the vibrations of the disk and the character of the electric currents to which they give rise.

MISCELLANEOUS.

Benjamin Smith, a Utica machinist, has invented an attachment signal for the telephone. It consists of a sort of target, and, every time a call is made, a red disk makes its appearance. If the party signaled is out, he will know of the call on his return. The invention has been patented. Engineering News Dec 13 1879

When it is considered that if this mischievous method of trying to gain the credit of an invention is tolerated, no man's original work will be safe, since it is in the power of any upstart to dispute it by fictitious proofs of this kind, it will be admitted as a working principle that only *publication* to the world should determine the authorship of an invention. We are far from meaning to imply that the American scratch claims in question are not genuine; thus far we believe they are, but the system is a pernicious one, and there is no saying to what evils it might lead if it be not nipped in the bud.

BLAKE'S MICROPHONE TRANSMITTER.

THE form of microphone designed by Mr. Francis Blake of Preston, Massachusetts, and recently introduced into this country by the Telephone Company as a transmitter for working their Bell telephone lines, is, perhaps, the most successful practical microphone which has yet been put together.

In all, or nearly all the microphones hitherto constructed one of the contact pieces is kept in a fixed position, while the other, being free to move to some extent, is constantly held in contact with this fixed piece, and is pressed against it with greater or less force by the vibrations of the diaphragm with which it is connected. In using an instrument of this form it has been found necessary to adjust the initial static pressure between its contact pieces or electrodes with great delicacy and care, in order to secure such a variation of resistance between them under the vibrations of the diaphragm as will enable the current to reproduce in a receiving instrument the sounds which fall upon the transmitting instrument. When such an adjustment has been secured it is easily disturbed by slight causes, such as a change in the temperature of the instrument or a trifling movement of some of its parts in relation to other parts.

By Mr. Blake's arrangement the proper adjustment is, however, easily secured, and is not liable to be disturbed in the practical use of the instrument. Both electrodes are supported in such a manner that they can move freely with the diaphragm. One of them may be attached directly to and be supported by the diaphragm, although it is preferred to support it in contact with the diaphragm from an independent support. The other electrode is so supported as to move freely, but is made so heavy, or is so weighted, that by its inertia it will offer a resistance to the slight and quick vibrations of the diaphragm, which will give a varying pressure between the electrodes and a consequent change in the resistance of the circuit. This second electrode is so supported that the initial static pressure between the two will not be sensibly affected by a change of temperature within the ordinary range of temperatures to which such instruments are exposed. It is placed on the end of a spring whose other end is connected to a lever, by means of which the proper initial pressure between the electrodes and against the diaphragm is obtained.

To secure contact between the electrodes, independently of the pressure against the diaphragm, the electrode next to the diaphragm is supported upon a spring which exerts its pressure against the opposite electrode.

The following drawings fully illustrate the apparatus: Fig. 1 is a plan of the mechanism attached to the top or cover of the box containing the microphone. Fig. 2 is a section of the box and mechanism on the line *x*, *x*, Fig. 1, and shows one of the terminals for making connections with the exterior circuits. Fig. 3 is a transverse section of the said box and mechanism on the line x^1, x^1, of figs. 1 and 2, and showing the terminals for making connections with the exterior circuits. On each of these figures A represents the box or casing in which the microphone is enclosed; the latter being for convenience attached to the cover or top A^1. B represents a metal ring or frame for holding the mechanism of the microphone. It is screwed to the cover A^1, as shown, and has two ears B^1, B^2. On the inner surface of the ring B is a narrow ledge or lip *b*, fig. 3, on which the disc or diaphragm C is placed. This diaphragm is formed as usual of a thin iron plate. A lining of paper or other suitable material is placed between it and the ledge or lip, and it is held in place by two springs n, n, attached to the metal rim or ring B, with their free ends pressing upon the back of the diaphragm near its centre so as to hold it against the ledge. Thin pads of india-rubber *a*, *a*, are placed between the ends of the springs and the diaphragm. By this method of holding the diaphragm in place it is less liable to be distorted by a change of temperature than when held wholly at its circumference. The centre of the ring and diaphragm is opposite the orifice E, fig. 2, in the cover A^1, through which the sounds enter the instrument. On the other side of the diaphragm and at its centre is placed one of the electrodes. It is a small metal bar or hammer *e*, fig. 2[1], one end of which rests against the said diaphragm. The other end is brought nearly to a point and is in contact with the other electrode e^1. It is desirable that it should be formed of or plated with some metal like platinum or nickel which is not easily corroded. It may be attached directly to the diaphragm, but, as stated above, it is preferred to support it independently, as shown, upon a light spring *c*, which tends to press it away from the diaphragm and towards the opposite electrode e^1.

This method of supporting the electrode *e* ensures its contact with the other electrode under some circumstances which otherwise would be liable to separate them and break the circuit.

The electrode e^1 is fastened to a weighted spring *d*, supported on an adjusting lever F by which the tension of the spring is regulated. This spring must be stronger than the spring *c* which supports the electrode *e*, and from its greater strength it tends to keep the electrode *e* in contact with the diaphragm. It may be made of a piece of a common watch-spring, and carries at its free end a weight *g* heavy enough to check very greatly the rate of vibration of the spring. This weight may be of metal, which may serve directly as the electrode, but better results are obtained by applying to it, at the point of contact with the other electrode, a piece of gas-coke, or a hard-pressed block of carbon *h*, such as is used in electric lighting. If the weight is a non-conductor, there must be a metallic conductor between the carbon or other electrode used and the spring or some other part of the circuit. The weight must be proportioned to the stiffness of the spring, a stiff spring requiring a heavier weight than a weaker one. The adjusting lever F, to an arm of which one end of the spring *d* is attached, is a stiff bar connected at one end by a stiff spring *j* to the ear B^1 of the ring B. The other end rests upon an adjusting screw G, placed in the ear B^2 on the opposite side of the ring. The spring *j* tends to force the lever F away from the diaphragm and against the adjusting screw G. The ear B^2, supporting the adjusting screw G, is drilled and slotted as shown in figs. 1 and 2, to prevent the screw from wearing loose.

The part of the lever F which comes in contact with the screw is inclined to the axis of the screw, as shown, so that when the screw is forced inward it will press the lever towards the diaphragm, and when it is withdrawn, the lever will, by the tension of the spring *j*, be forced away from the diaphragm. The outer end of the screw extends into a hole *l* through the casing, and is fitted to receive a key by which it can be turned to adjust the lever to a desired position.

The pressure between the two electrodes and against the diaphragm obviously depends upon the position given to the adjusting lever by the adjusting screw G, but it is evident that, as this pressure can be increased or diminished only by increasing or diminishing the tension of the spring *d*, the changes in the pressure by turning the screw will be much less rapid than they would be if the electrode were acted upon directly by the lever or the adjusting screw. Hence a proper adjustment of the initial static pressure between the electrodes can be much more easily obtained through the agency of the spring *d* than without it. It will also be seen that this pressure will not be sensibly affected by any slight change in the position of the electrodes which might arise from the expansion or contraction of any part of the apparatus under a change of temperature. On the other hand, it will be seen that if the diaphragm is thrown into the rapid but slight vibrations caused by sounds, the spring alone would yield to them so readily as to give but little change of pressure between the electrodes within the range of the vibrations, but by reason of the inertia of the weight, the tendency of the spring to follow the vibrations of the diaphragm will be checked, and a greater range of pressures between the electrodes will be obtained. At the same time, it will be readily seen that the changes of pressure will be very different from what they would be if the electrodes were supported rigidly and could not yield to the movements of the diaphragm.

An additional improvement is gained by supporting that electrode on the aforesaid light or independent spring, which keeps it in contact with the electrode e^1, for it not unfrequently happens, when the intermediate electrode is attached directly to the diaphragm, that a too rapid vibration of the diaphragm, or some other disturbance in its vibrations, will throw the outer electrode out of contact with the intermediate electrode, and thus break the circuit; being audible beyond the desired limit. A monthly rental is charged for the use of this system.

Now that the ice is broken, we anticipate that the telephone will be taken up with the customary energy of our countrymen, and we hope soon to see the whole of London, as well as other large cities, divided up into districts, each furnished with its central telephonic station.

ON LIGHTNING PROTECTORS FOR TELEGRAPHIC APPARATUS.

By WM. HENRY PREECE, Electrician, General Post Office.
(Read before the British Association.)

FOR many years it was not the practice in England to protect telegraphic apparatus from the injurious effects of atmospheric electricity because the damage done was so insignificant, and because the remedy was found to be worse than the disease.

But as telegraph systems increased—as the country became enveloped in one vast network of wires, it was found that the damage done became considerable, until, in fact, about 10 per cent. of the apparatus in use were in one year damaged.

Lightning protectors then became essential. Many forms were tried, based on the fact that when a discharge takes place through a non-conductor, such as dry air, at the moment of discharge the resistance along the line of discharge is practically nothing, and, therefore, all the charge is conducted away. According to Faraday, "the ultimate effect is exactly as if a metallic wire had been put into the place of the discharging particles." (*Researches*, series XII., 1406.) Most of those tried failed.

The survival of the fittest has been exemplified in the "plate" protector. In this form—one of the earliest introduced—one thick plate of brass is in connection with the earth, and another similar plate in connection with the line is placed above it, but separated from it by paper, or by insulated washers. The lightning, on entering the wire, bursts across the paper, or air space, in preference to passing through the apparatus, and thus escapes to earth.

An important modification of this plate discharger has been made by Dr. Werner Siemens, who, by serrating, or grooving with a pointed tool the opposing faces of the two plates at right angles to each other, converted them into a conductor, which was supposed to be one composed of an infinite number of opposing points. The remarkable action of points in facilitating discharge is well known, and their introduction into lightning protectors occurred very early in the annals of telegraphy, by Mr. C. V. Walker, F.R.S.

Messrs. Siemens' arrangement, very pretty in theory, never carried conviction of its value in the mind of the author, because protectors, so prepared, never singled themselves out as evidently superior to others that were not so prepared; and while the intersection of the grooves certainly formed mathematical points, they did not form physical or mechanical points, and it is upon the action of this

Manufacturer & Builder November 1879

Latest Telephone of Edison.

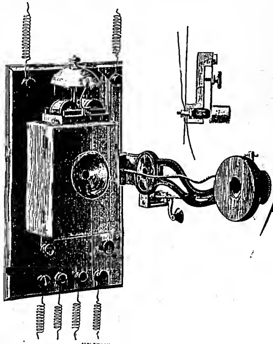
One of the most interesting experiments exhibited before the meeting of the American Association for the Advancement of Science, was that of Edison's latest improved electro-chemical telephone. It was attached to a stand in front of the platform, in the large room of the town hall, containing some 2,000 or 3,000 persons, and this telephone was found so unrivalled for loudness of speech that every person in the hall could hear what was said at the other end of the line, and transmitted to the telephone by an ordinary conducting wire. This is quite a feat, and an enormous step in advance of the Bell, Gray, or Phelps telephones, which require the observer to place his ear close against them, and even then the speech is not always distinctly heard.

The principle on which this telephone works is quite different from any of those mentioned, as the receiving instrument requires neither electric batteries nor magnets of steel or of coiled soft iron. The principle upon which it works is a variation of friction, which takes place when a conducting point is sliding over a surface, while an intermittent electric current runs from the point to the surface, or *vice versa*.

Edison discovered this principle a long time ago, and at first tried to produce by it the points and dots of the Morse alphabet, without using electro-magnetic attraction. He made a point which touched a revolving cylinder, and so adjusted that the friction of the revolving cylinder pulled it forward, overcoming the tension of a spring which held the point back; every time the current passed the friction between the cylinder and the point became very small—in other words, the current made the surface temporarily so smooth that the spring caused the point to slip back; when it slipped back a simple leverage produced a contact, making a point or a line, in proportion to the length of time the current lasted, while as soon as the current ceased the point was pulled forward again by the revolving cylinder. It should be understood that the whole extent of the motion of this point was only ¼ of an inch, or even less, which was quite sufficient to make the telegraphic dots and lines, a point being formed on the ordinary strip of travelling paper every time the current lasted only an instant, and a line in length in proportion to the time the current lasted.

In applying this idea to the telephone, Edison attached the point to the diaphragm, and when the cylinder is turned the friction is sufficient to pull the diaphragm forward; but when the slightest intermittent current is passed, the frictional surface of the cylinder is changed into a smooth surface in regard to the point, and the diaphragm pulls it back. It does this for every wave of the current, each of these therefore producing a single vibration of the diaphragm, and hundreds are required for every word. When no current passes, the point is pulled forward by the revolving cylinder, and the elastic diaphragm kept uniformly on the stretch; when currents pass, the diaphragm becomes able to pull the point backward as often as an electric wave passes, and this causes vibrations equivalent to the velocity and character of the waves.

Understanding the principle upon which to base such a telephone, the practical question was, What are the best materials for the cylinder and the point? After numerous experiments Edison found that precipitated chalk, solidified at great pressure, was the best material for the cylinder, and for the point a piece of platinum faced rubber. He also found that the chalk must be wet, and, after trying hundreds of solutions, he at last found that it was best to saturate the chalk with an alkali or its phosphate, and finally that the best solution of all was a diluted solution of hydrogen disodic phosphate.



EDISON'S NEW TELEPHONE.

In the adjoined engraving the receiving instrument is represented at the extreme right, and so hinged that it can be turned out of the way when not in use. It has a small crank (seen below) that is turned around when the reception of a message is expected; this crank is connected by an axis to the revolving chalk cylinder in the little receiving box seen at the extreme right; this box is also connected by the isolated conducting wires seen above the straight axle connected with the crank. The transmitter is the square box seen at the left, with its mouth-piece in front and the call-bell on top.

The details are represented in the small figure at the upper right-hand corner of our engraving. A vulcanite arm is secured to the center of the mica diaphragm by means of a small bolt, which is connected with one pole of the battery by a piece of metallic foil or very thin copper wire. The head of this bolt is platinum-faced, and sunk deeply in the vulcanite arm, the same cavity also containing a piece of carbon pencil, such as is used for electric candles. The carbon fits the cavity loosely, and is rounded at both ends; its outer end is pressed by a platinum-faced spring secured to the outer end of the vulcanite arm; the spring carries at its free end, exactly opposite the piece of carbon, a brass weight, and the pressure of the spring upon the carbon is regulated by the small set-screw. A wire or piece of copper foil, connecting with the spring, completes an electric circuit, which includes the primary of an induction coil contained by the rectangular box. The secondary wire of the induction coil is connected with the telephonic line, and a tertiary coil which envelops the secondary is connected with the rubber and chalk cylinder of the receiving instrument. Below the transmitter box are two keys, the right-hand one being used for signalling, and the left-hand one for completing the tertiary circuit when a message is received.

Talking Over Two Thousand Miles.

Under this caption was reprinted in the Journal of the Telegraph, of December 1st, from the *Bethlehem (Pa.) Times* an improbable statement that Mr. Robert Packer, "Superintendent of the Pennsylvania Railroad," while traveling in Nebraska, had conversed with his wife and friends at his home in Sayre, Pa., two thousand miles distant, by means of a telephone. Tel - Journal Jan 1/80

Since its publication, the *Scientific American*, which also reprinted the statement, learns, it says, on good authority, that, though Mr. Packer's friends received his communication by telephone, it was not so sent by Mr. Packer. The message was sent from Nebraska to Mauch Chunk, Pa., by telegraph; thence it was telegraphed to the Sayre office of the Pennsylvania Canal and Railroad Company (of which Mr. Packer is superintendent), and from there it was transmitted to Mr. Packer's house by telephone—falling short of the newspaper report of the telephone's performance by some nineteen hundred and ninety-nine miles and a fraction.

The First Edison Loud-speaking Telephone introduced into Birmingham has been used to connect the Camp Hill Works of Messrs. Crichley & Co., stove, grate, and fender manufacturers, with their showrooms and offices in Cannon Street, Birmingham, a distance of about a mile and a half.

Ironmonger 22 Nov 1879

NEW RESEARCHES ON THE THEORY OF THE MICROPHONE.

By Dr. Julian Ochoswicz.

Two distinct hypotheses have been put forward to explain the phenomena which occur in the ingenious discovery of Mr. Hughes. The one, exclusively molecular, supposes dilatations and contractions of the molecules in certain partially conducting bodies, to take place under the influence of sonorous vibrations, in the microphone itself. *Changes of density* correspond to the increase or decrease of the resistance of the circuit, and, consequently, to a proportional production of sounds. This hypothesis bears a certain analogy to the phenomena which take place in selenium under the influence of light and radiant heat.

The other, partly molecular and partly mechanical, rests upon the discovery, made some time ago, by M. du Moncel, and according to which the increase and decrease of resistance are due to changes of pressure in the electrical points of contact. These changes being produced by the pressure of the vibrating air, there results an equivalence of causes and effects.

In basing my theories on experiments made with a very great number of microphones, since the first appearance of this discovery, I shall endeavour to prove that, if one of these hypotheses is entirely erroneous, the other is only superficially true.

In the first place:

1. When the carbon rod is immovably fixed by any cement, wax for example, without submitting it to any pressure, the microphone remains inert under the most powerful sonorous effects. This would be impossible if it acted by molecular action only and not mechanical.

2. The microphone can be placed in a tube of glass, lightly suspended by means of a fine wire, and the air exhausted in the tube without affecting its microphonic effects. It is evident that, in this case, the waves of air can have no influence upon the density of the carbon, they only act mechanically by shaking the whole apparatus.

3. It is impossible to construct a microphone of a single piece of solid carbon, presenting firm contacts, which do not prevent molecular influences, but which render impossible the action of sonorous waves, of contacts, and of shakes, on the current which traverses the carbon.

It appears to me, then, that we have these sufficient reasons for entirely rejecting the exclusive molecular theory.

Again:

1. The lateral pressure exercised on a compact electric conductor (metal, carbon, &c.) placed in a telephone, does not produce any microphonic action.

2. A longitudinal pressure exercised on the rod of a microphone by means of a thumb-screw, can modify within certain limits without altering the action of the apparatus. This is only the *timbre* which alters the intonation. But the same effect can be obtained without change of pressure, by the simple fact of changing the points of contact. If the pressure is augmented, the apparatus loses its sensibility at the same time that it loses its faculty of vibrating mechanically; but the single fact of an augmentation of pressure has no connection with any microphonic phenomenon. This experiment relates to a microphone with a membrane.

3. Apparatus can be constructed in which the pressure remains the same, and which nevertheless acts as a microphone. (See figure.) It is hardly rational therefore to consider pressure as the essential cause of microphonic phenomena.

It is, however, an accidental cause, for when the sonorous waves strike the movable part of the apparatus, the pressure which it exercises on the support changes; but this is not from the fact of the pressure causing the differences of resistance; it is from another fact, often parallel to the first, but which differs from it.

9

In order to understand this better, let us consider the apparatus in its simplest form, as shown by fig. 1.

Fig. 1.

Two short pieces of wire, in circuit with the microphone and telephone, are stretched across one another as shown; the current passes at the point of crossing. It is *at this point only* that the microphonic action takes place. When one of the wires is caused to vibrate from any cause, a noise or very strong musical sound fills the room in which the telephone is placed. If the wires are good conductors the action of the apparatus has two phases: the current passes when one wire touches the other, it does not pass when the reverse is the case. There is then a *simple and complete interruption of the current*, and, in consequence, this microphone, like the transmitter of Reiss, like the singer of Mr. Pollard, &c., can only transmit simple sounds. This first category embraces all the microphones in which the contact is effected at a single point. I have obtained better results of the kind with a bladder membrane and sharp point. The electric communication was ensured by a little strip of tinfoil glued on the membrane. With a small bichromate battery the tune could be heard all over a room. Strictly speaking, there is in these simple apparatus certain graduations of action between the limits of full intensity and of complete rupture of the current, and one can understand that sometimes the *interruption is only partial. It is then the alteration of the points of contact* which plays here the principal *rôle. The intensity* of the sounds depends upon the greater or less number of these points; the number of successive interruptions of the same contacts determines their *pitch*, and the nature of the changes their *quality*. In fact, the successive and simultaneous combinations, periodic or non-periodic, of all these changes determine their *articulation*. It is sufficient to compare the traces of the words in the phonautograph, the logograph, and the phonograph to convince oneself that it is, in these apparatus, only a reduction of *quality* to quantity. I am even inclined to believe that this reduction is very simple, and that a series of combinations in times and in spaces of *three material points of contact* is sufficient to produce an equivalent to all our articulate sounds. It would be difficult to relate all the experiments and inferences which have led me to this supposition, but I give them for what they are worth, and now pass to the third category.

The principle of the change in the number of points of contact caused by pressure allows us to consider the different resistances of the microphonic circuit, and explains the action of the majority of microphones, but it does not explain all.

It is possible to construct, in fact, microphones in which no alteration of pressure will produce a variation in the numbers of points of contact, but which, nevertheless, work well.

Fig. 2.

Suppose a little cylinder of carbon, *a* (fig. 2), fixed horizontally to a membrane, M M, and sliding on another small cylinder of carbon, *b*, movable about its axis. If the cylindrical form of these two pieces is perfect the pressure and the number of points of contact remain the same. If this is not so, as would practically be the case, then the *rôle* played is different; it is *the* length of the route traversed by the current in the bad conductor. Whilst the membrane vibrates, its distance from the carbon *b* diminishes or increases, and there is then a change in the number of the points of resistance crossed.

It is this class of apparatus to which belong the liquid telephone transmitters of Gray, Bell, and Palet, where the change of resistance in the circuit results from a layer of liquid more or less thick, which is to be traversed by the current.

It is very difficult to separate the two principles one from the other, but it is possible to determine the preponderance of the one or the other, or still better their parallelism. Suppose, for example, that the two cylinders of carbon, *a* and *b*, were replaced by two plates of the same material, and that *b* remains immovable, the two actions would be equal and opposite. The same complication presents itself in the microphonic transmitter of M. Righi, where the metallic disc of the membrane plunges in the powder of plumbago mixed with powdered silver.—*La Lumière Electrique.*

American Inventor

The Telephone Abroad.

Dec 1879

The disinclination to adopt American institutions not infrequently deprives the people in foreign countries of the benefit of facilities and conveniences which in the United States are regarded as indispensable. Our system of fire-alarm telegraphs which is here so generally and successfully introduced, has never, we believe, been adopted elsewhere, and the cumbersome and inefficient systems of notifying the existence and localities of fire are retained. The telephone was at once adopted and put to practical and extensive use here, while abroad, except in Germany, very little use has been made of it as yet.

The system of telephonic communication which has proved to be so popular, is just being introduced in England and France, but in every instance, we believe, due to American enterprise. It will no doubt require some time, even after they are established, to educate the public to use them to any considerable extent. Perseverance, however, will in time overcome unreasonable prejudices, and we shall probably within a few years see the telephone in use in all the great business centers of Europe. Their advantages are so obvious, and the necessity for prompt communication so pressing, that once introduced they cannot fail to meet with more prompt appreciation and practical adoption as localized institutions than has usually been the case with telegraphic improvements originating in this country.

A NEW TELEPHONE.

Dec 27-79

In the telephone shown in the annexed engraving the inventor has made use of Jamin laminated U-magnets to secure great magnetic power with little weight. The ends of the magnet are cut off diagonally, and the poles are each surrounded with a helix of fine insulated copper wire connected as in an electro-magnet. Two of these magnets are attached to an elliptical hoop, which surrounds the head and supports

NOVEL TELEPHONE.

the diaphragms and ear pieces. Each diaphragm carries a light triangular armature, which fits the poles of the magnets and nearly touches them. The telephones are connected with each other and with the line. The operation is similar to the Bell telephone. The instrument shown in the engraving is arranged as a receiver to be used with any of the ordinary transmitters, but it may be arranged as a transmitter.

Mr. Andrew C. Hubbard, of Danbury, Conn., is the inventor of this telephone.

Oct 15 Telegraphic Journal 1879

Edison's telephone, of the form illustrated on another page, is giving great satisfaction in France, where it has been tried at the Central Telegraph Ad-ministration and on several railway lines. The Administration experiments were undertaken at the request of M. Cochery, minister of posts and tele-graphs, and they were made between Paris and Versailles, a distance of 13 miles, and on other shorter suburban lines. Although more than 100 sets of Morse and Hughes instruments were at work in the same room, and ordinary traffic was passing over the wires next to the telephone circuit, the Edison apparatus is said to have done very well. On the Northern Rail-way, M. Lartigue, the engineer, has installed a loud-speaking telephone from Paris to Creil, a distance of 31¼ miles; another, *vid* St. Quentin, a distance of 40 miles; and a third from Paris to Amiens and returning to Creil, a length of 142 miles. On the first two lines the vocalisation is all that could be desired, but on the longer one it is feeble, and speakers require to raise their voices, and sometimes to repeat, in order to be heard. On the Eastern Railway several shorter lines, as from Paris to Meaux, a distance of 25 miles, have been fitted with these telephones successfully.

THE TELEPHONE IN FRANCE.

SPREAD OF THE SYSTEM—THE GOVERNMENT DEPARTMENTS TAKING HOLD OF IT—FUSION OF THE RIVAL COMPANIES.

Herald Nov 24 1879

[illegible] Nov. 7, 1879.

The war which threatened to break out between the three telephone companies (all American) seeking a foothold in Paris has been nipped in the bud by a compromise which will doubtless be as much for the interest of the public as for that of the companies themselves. To go back a little, the success of the Gower telephone as described in the HERALD of July 16 led to renewed activity on the part of Mr. Edison's representatives and also to the development of a third party under the lead of several gentlemen from Chicago, the latter seeking to employ forms of telephones already introduced by the Bell Company in the United States. Having granted a concession to run wires to the Gower Company the government found itself under some pressure to do the same for the others, and finally did so, expressing a hope at the same time that some way of uniting the several interests would be found. This has now been reached, and a visit to the large and elegant quarters fitted up by the Gower Company shows that the introduction of this latest American novelty is fairly under way. The facts and figures are of interest as illustrating the progress of American enterprise abroad. The new combination is entitled The General Telephone Company—Edison, Gower and other systems. The honorary directors are Thomas A. Edison, of Menlo Park, N. J., and Frederic A. Gower, of Providence, R. I. It was intended to include the name of Professor Bell, but this was found inexpedient, because the Bell telephone patent has been declared invalid in France owing to previous publication of the principles of the instrument in this country.

The capital of the concern is fixed at 10,000,000f., of which about one-half is devoted to the purchase of the Edison, Gower and other interests, and the rest to construction and maintenance. The capital is stated to be all subscribed and the shares are already held at a premium. The actual management of affairs is in the hands of a board of directors, with an executive committee, of which Mr. Cornelius Roosevelt, of New York, is a member. The central office is located at the headquarters of the Gower Company, No. 66 Rue Neuve des Petits Champs, where active preparations are in progress.

THE METHOD OF OPERATIONS.

The premises occupy the upper floor of a spacious building and comprise ten rooms, about fifteen feet square, a reception room 30 by 30, and an operating room 40 by 20. Half the smaller rooms are devoted to offices and the rest to Mr. Gower's laboratory and private apartments. The operating room is divided along its walls into compartments, on the system of the French telegraph offices, with a central switch board for connecting wires together, and a desk in the middle of the room for the chief operator. It is finished in American hard pine, and the yellow tint of the wood is already crossed with wires in every direction. The estimated capacity of this room is two thousand lines, and some six hundred of these are already secured by the union of the telephone interests. The subscriptions include the leading journals, bankers, physicians, theatres, hotels and so on, quite upon the American plan. M. Emile de Girardin has already an Edison telephone from his house near the Arc de Triomphe to the Avenue de l'Opéra, while the Rothschilds, the Crédit Mobilier, the Prefect of the Seine, the Minister of Posts and Telegraphs, and a long list of lesser notabilities in the Paris world have installed the instruments of Mr. Gower. The office of the NEW YORK HERALD in the Avenue de l'Opéra will naturally be among the first to adopt the system and will offer its fullest advantages to those having business to transact there as well as to the habitués of its reading rooms. Mr. Gower proposes one or more special wires for the HERALD service so that information can pass without delay between the HERALD office and the telephone centre at all hours. The facts connected with the telephonic system are familiar enough to the New York public, but to the Parisian mind it still savors of wild fiction that an American in Paris wishing to find a friend's lodging place should step into the HERALD office and in full minutes be able to make inquiries regarding it of all the principal hotels; or without leaving his easy chair secure places at the theatre, make appointments with a friend, ascertain if the American steamer is arrived at Havre and thus transact his business generally. The idea is still too startling, and people are found who subscribe to the system with express provision that it shall first be proved a practicable means of communication. But the projectors of the system go on with their plans, and the uniform of the messengers of the "Téléphone Gower" is already to be seen here and there on the boulevards.

USES OF THE SYSTEM IN FRANCE.

Aside from the "district system," so familiar in America, there are several interesting uses of the telephones peculiar to European life. In Paris every house, public or private, has its *concierge* or janitor on guard at the entrance, while but few have any prompt means of communication from the *concierge* to the tenants on the floors above. Speaking tubes are a costly luxury and bells are of limited application. Even in a hotel like the Continental, where bells and tubes have been made a study, it has been found that two of the Gower telephones put in, wire and all, in two hours, give greater satisfaction than a speaking tube which occupied two weeks in construction and cost twenty times as much as the telephones. Large concerns like the Crédit Foncier, the Crédit Mobilier, the Bourse and the Hôtel de Ville report the same experience. Let us take again that of the coast guard. As everybody knows, the western and northern coasts of France are provided with coast guard stations, within sight of each other and connected by telegraph with the nearest towns. At intervals, also, there are batteries and military posts, though the latter are more numerous along the eastern frontier. As a telegraph force at each of these thousand points is expensive, the government was inclined to welcome the advent of the telephone until it was found that it, too, required a battery and some electrical knowledge. But with the advent of the Gower telephone this last objection was obviated, for without the aid of a battery the instrument not only sounds a whistle like a distant fog-horn, but can be made to release a spring that starts a clockwork bell which will produce any amount of sound required. In the public telegraph service it was first thought that telephones would be of no great use in the presence of a well organized system of "old-fashioned telegraphs," as Mr. Gower puts it.

THE TELEPHONE IN GERMANY.

But Dr. Stephan, the telegraph director of Germany, has put in operation some six hundred telephone stations, and France cannot afford to be behind in the progress made in this direction. Experiments show that for distances under twenty or thirty miles, where the wires are not numerous upon the same poles, the Gower telephone (which is, after all, only a highly developed form of the original Bell instrument) is practically effective for common uses without the aid of a battery. The Belgian government reports a satisfactory test between Brussels and Ostend, seventy-seven miles, but this is regarded as exceptional. So it follows that any village large enough to have a post office may receive its telephone for communication with the nearest telegraph station, and that without requiring any knowledge of the principles of the instrument on the part of those who use it, this last being an important feature from the European standpoint. The use of private telegraphs has never become common in France or Germany as it has in England, and is comparatively trifling to what is known in the United States. So the telephone now finds this field clear and makes known for the first time the very want which it supplies. For military purposes this latest scientific improvement has already taken a firm hold. It has been found that a cavalryman can hang a Gower telephone upon his saddle bow, strap a reel of wire upon his back, and run out a kilometre (three-fifths of a mile) of telephone line, attach the instruments and begin conversation in sixteen minutes from the time of starting. A strong steel wire is used, and to test its strength batteries have been driven over it at full gallop without breaking the communication. On one occasion a file of soldiers was detailed to use the instrument steadily, eight hours a day for an entire week, without developing any weakness in the system. It is scarcely necessary to add that American inventive genius now holds a high place in French military estimation. And in this whole telephone business one of the facts most impressive to the European scientific mind is the freedom from any allegiance to theory characteristic of American invention. Theory and law in Europe are everything; in America it is the demonstrable fact that rules the situation. Professor Bell developed a speaking telephone and explained its theory, while Mr. Gower, his friend and pupil, produced a form of the instrument of which Professor Tyndall said, with a smile, that "no theory could have led to these conclusions." And so long as this striking difference exists we may expect to see American inventors pointing out the way to fresh employment for the surplus millions of European capital.

PROGRESS OF THE TELEPHONE IN FRANCE.—Three telephone companies have been formed in Paris; they have now been consolidated, and a capital of 10,000,000 francs paid in, half of which is devoted to buying the patents and the interests of the three old companies, and the other half for expenses of offices, wires, apparatus, etc. Six hundred lines are already in operation, and others are in course of construction.

THE TELEPHONE EXCHANGE.

As the Telephone Exchange has now become a reality, being actually at work in London and some provincial towns, a few notes upon details will not be without interest, especially as there has been some misconception as to the appliances adopted for the work of intercommunication by the telephone. In its simplest form the Telephone Exchange consists of a central office from which line wires extend to the offices or residences of its subscribers; but it is obvious that in such a place as London the central office may be connected with any desired number of local exchanges, each complete in itself, but having communication with all the other local offices through the central station. All that is needed is a multiplication of the appliances used for the simple exchange, and an explanation of the latter will, therefore, suffice for all purposes. In the central office of a telephone exchange, then, there is a switch-board for, say, every 30 subscribers, and an attendant who is continually on the watch for signals from the members of the exchange. The number of switch-boards will obviously depend upon the number of members, and clearly the number of subscribers to one switch-board, must depend upon the amount of talking that they wish to do. If all 30 subscribers want to communicate at the same time, the 30th will be getting impatient before his turn comes round, unless each member *is* limited to a few minutes' possession of the line; and consequently where such an arrangement will not suit, the alternative is a fewer number of lines to one switch-board. Each member of the exchange has a transmitting and a receiving telephone in his office, and each switch-board at the central station is similarly equipped. Along the upper part of the switch-board is a row of little metal shutters, which when they are closed cover up the figures representing the names of the subscribers; and along the bottom of the board is a row of metal-tipped pegs, which fit into holes made in the intervening space. Suppose now that member No. 1 wishes to be put into communication with No. 7, he rings the bell in the central station by putting his switch to the bell. At the same moment as the bell rings, the little shutter falls down and discloses the number of the member who wishes to use the line. The attendant then goes to the telephone and asks what is wanted, and on receiving the answer, in our supposed case that No. 1 wishes to speak to No. 7, he signals 7 by bell, and on obtaining attention informs him that No. 1 wishes to speak with him, and that he will put him in communication. That is effected by putting the metal pegs belonging to Nos. 1 and 7 respectively into holes in the centre line of the switch-board, which has the effect of connecting line No. 1 with line No. 7, and the two members of the exchange can now converse together without any fear of being overheard. The attendant puts up the little shutters, which being hinged at the bottom, fall over on to the switch-board, and will now serve as a signal to him that the conversation is ended without having a special wire for the purpose. No. 1 and No. 7 having finished their business, signal that fact to each other by their bells, and at the same time the attendant is informed of the fact by the falling over of the little shutters. As a matter of precaution, he will probably call to one of the members before restoring the switch-board to its normal state, but the fact of the shutters having fallen will be considered as a sufficient signal for him to disconnect wires No. 1 and No. 7, and attend to the next applicant. The operations are precisely the same no matter how many local exchanges may be connected to the central one, but of course, just as the pegs must be shifted at the central station, so they must also be shifted at each of the central offices of the local exchanges. The instruments chiefly used are the Bell and the Edison telephones, or a combination of the two, the Bell being preferred for transmitting and the Edison for receiving. So far as merely receiving messages is concerned, it is easy to understand that the Edison would be chosen by many persons, for while it is necessary to place the Bell instrument to the ear, the Edison can be heard at a distance if clockwork has been provided to revolve the chalk cylinder. That, however, necessarily adds to the expense, and as a rule the instrument intended for occasional use only will need the hand of the listener to turn the crank attached to the chalk cylinder. For press purposes, however, and in places where long messages are frequently received, the cylinder will be rotated by clockwork or rather by a train of wheels and a weight. Experiments have recently been made with the loud-speaking telephone of Edison to test its suitability for transmitting messages between a reporter at the House and a compositor at the printing-office. A shorthand writer at one end of a line wire reading slowly from his notes can be understood and followed rapidly by an operator sitting at a composing machine, but until more practice has been made it would be premature to speak of the results as altogether satisfactory. With everything prepared, however, paragraphs have been set in type from the verbal message received by the telephone, and the plan is otherwise so advantageous in late work on newspapers that every effort will be made to develop it. Telephone wires will doubtless be laid on between the House of Commons and the clubs and the principal newspaper offices, for in the one case, information as to the progress of a debate can be transmitted as frequently as necessary, and in the other, the latest news—such as the result of a division—can be sent up to the very last minute before going to press. That could of course be done by telegraph, but the telephone is much simpler, quicker, and in the long run more economical. The present arrangement for telephone exchanges may be fairly regarded as crude and imperfect: improvements are sure to be suggested as the defects become apparent in continued usage, and we are therefore not too sanguine in believing that before many more years have passed the Telephone Exchange will become a recognised institution of a busy city, and the rent payable to the company one of the legitimate expenses of a business.

VOL. XXX.—NO. 771.

THE "Edison Telephone Company" have opened offices at Royal Exchange Square, Glasgow; and the "Telephone Company" at 72, Queen Street, in the same town.

Telegraphic Journal Dec 1 1879

Detroit Post Tribune Jan 11 — 1880

MUSIC BY WIRE.

How Some of the Telephonists While Away the Dull Hours—Popular Appreciation of the Telephone—Work at the Central Office.

On Saturday night a POST AND TRIBUNE reporter climbed to the upper floor of the telegraph block on Griswold street, where the telephone exchange is located, and was ushered into the room by George Stockwell, a bright eyed young fellow who stands guard over the apparatus during the long hours of the night. When the success of the telephone was assured as a transmitter of the human voice it speedily took a popular hold upon the public. Business men at once saw that it would come into general use, and when the telephone exchange was established the most enterprising merchants gave it their patronage. Eventually nearly every leading business house in the city connected itself with the exchange and soon private houses followed their example. Under the new order of things a merchant can communicate with almost any part of the city, without leaving his office.

The instruments are ranged along the wall at the exchange, and during the day there is an operator for each circuit. These operators are boys selected on account of their intelligence and the facility with which they are enabled to answer calls. The apparatus is so arranged that when a call comes in, the person calling is located by an annunciator similar to those in use in hotels. The operator responds with a "hello," and on ascertaining who the person calling desires to communicate with calls the party, and by adjusting a switch places them in communication. He then tells them to "go ahead," and when they have ceased talking "cuts them out." The busiest time at the exchange is between 3 and 4 o'clock in the afternoon, when there are many calls, and the boys are kept on the qui vive to answer every summons.

At night there is less business. The stores, banks and lawyers' offices are closed and the telephones are out of service. In response to the reporter's query young Stockwell said the newspaper offices were the principal callers at night. Occasionally there comes a summons for a doctor or undertaker with now and then a call for a coupe or district telegraph messenger.

"Perhaps you would like to hear some music," the young man suggested.

The reporter said he would, and the operator stepped to the instrument and quickly manipulated the key board. Back came the responsive click, click, and Stockwell said, "Will you give us some music?"

"Yes," was the response, "wait a minute."

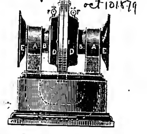
The reporter asked who were to furnish the music, and was told that Messrs. Griffith and Jamison, employes at the Michigan Central slip dock, two gentlemen who passed their leisure and whiled away the dull night hour with violin and mouth-organ. Placing his ear to the tube the reporter could distinctly hear Mr. Jamison tuning his violin at the dock a mile or two away. Then he heard him say to Mr. Griffith, "You play something while I finish tuning." In the meantime Mr. Hawley of the Russell house, J. W. Caldwell, the druggist corner of High street and Grand River avenue, and patrolman Splane, the officer on duty at the district telegraph office were, at the suggestion of the reporter invited to enjoy the concert. Finally all were ready, and after Mr. Griffith had played a very pretty air on the mouth-organ he and Mr. Jamison entertained the listeners for several minutes with duets. Not only could the airs be plainly distinguished, but every note was heard just as distinctly as if the players were in an adjoining room. At last the performers announced that they must go to work, the listeners thanked them for the entertainment and all bade each other good night.

13

DUPLEX TELEPHONE.

[16289.]—I now proceed to describe my duplex telephone referred to in the account that I gave of certain experiments with a phonograph. The principle is that of subjecting a single diaphragm to the action of a magnet and coil on each side of it, and *vice versâ*, to affect two magnets and their coils by the one diaphragm. The instrument as constructed is shown in the figure.

English Mechanic oct 10 1879



A A are the north and south poles of a horse-shoe magnet. This magnet is in reality double, and the ends near the poles are bulged out so as to embrace short pieces of soft iron tube marked B B. On the inside ends of these tubes are slipped the usual bobbins containing the wire coils. These cannot be seen, as they are inside the circular box D. This box is in two halves screwed together with the diaphragm between them. The outside ends of the tubes carry mouth-pieces E E of the ordinary form or nearly so. You thus speak through these two pieces of tube which, by being embraced by the magnets, become magnetised themselves, by induction. The wires of the two coils are connected to the binding screws, of which there are of course four, though only the two nearer ones F F are visible in the figure. Several interesting experiments have been already made with this instrument. It was, in fact, with this that the phonograph was used as described in my former letter, though not quite in its present form.

If one magnet and coil be properly coupled up to the other so as to bring both into action, it is found that the loudness of the voice at a distant (ordinary) telephone is much greater than when only one coil is used.

If two persons speak or sing simultaneously, one into each mouth-piece, the diaphragm will respond to both sets of vibrations, and both voices will be heard at the distant telephone. So two people at the same time can hear words received from the single distant telephone.

Again, by coupling an ordinary telephone A with one coil of the "duplex," and another B with the other coil of the duplex (there being no direct connection between the wires of A and B) conversation can be easily carried on between A and B. This would be naturally expected, as the diaphragm receives and "passes on" the vibrations, but in appearance it looks at first sight rather odd. I propose, as soon as I have time, to make experiments with a battery introduced into one of the circuits, also with the microphone as part of the arrangement. Should I obtain any new or interesting results I will communicate them.

Plumb-bob.

Priority in Telephone Matters.

Dr. Cushman, an able electrician, of New Lisbon, O., experimented twenty-five years ago with various kinds of telephones. He was recently interviewed in regard to his experiments, and the result, as published in the *Youngstown* (O.) *Vindicator*, again shows that nothing is more incorrect than to attribute the invention or discovery, as it now stands, entirely to any one individual. In regard to Dr. Cushman's claims, we extract from the paper mentioned the following statement made by him:

"In the year 1851 I was engaged in getting up some apparatus to protect telegraph instruments from the effect of lightning, when I discovered that I was receiving a sound, as of peeping frogs some several miles distant. This led me to look into the matter, and between that year and 1855 I got up some experiments with practical results. In fact, in 1855 and 1856 we made practical use of what may now be called the electro-magnet telephone. I did not get articulation as well as it is now obtained by Bell and others. My apparatus was rude and cheap, and I used different kinds of heads or diaphragms.

"In those early days and years of telegraphing we did not have time to stop and talk to reporters, as now. I find, however, in an old scrap-book, an attempt to give a description of a system gotten up by myself, of reporting trains upon railroads. This was by using the whistle and bell at different points on the road. In this way each locomotive would report itself. I was about to say that the only thing the newspaper man was right in, was the manner in which I constructed lines in this reporting system—the magnet, with metallic diaphragm enclosed in a box with ground wire line, and all that goes to make the Bell telephone, but in a rough state. In 1855 we used the same in principle, making such a practical use of it as to establish our claim as an original discoverer, provided no one had made use of the same prior to that date. The law does not compel a person to patent what he invents or discovers; but on the other hand it is a good defence to an action for the infringement of a patent, that the thing secured by the patent was not originally discovered or invented by the patentee, but had been in use anterior to the supposed discovery of the patentee. Neither would a mere change in form or proportion, or substitution of mechanical means or equivalents, in any one or all the elements producing the same result, constitute a substantial defence within the meaning of the patent law. In fact, in order for a plaintiff to recover for a violation of his patent, it must be shown that he was the original inventor in relation to every part of the work. The use we made was not mere experimenting.

"There has been a large number of patents issued on telephones. The Patent Office has had quite a harvest. The old stethescope, with a dried bladder drawn over the end and a string tied to the other, forming a string line from the house to the barn, as far back as 1834, has not escaped one or more claims among the batch issued."

To the above we may add that we found a description of a telephone in the German scientific journals in 1864. This was a form intended to convey musical tones, namely, the pitch and rhythm of sounds correctly. We had several of these instruments constructed, and experimented with them about that time in the Polytechnic Club of the American Institute. We made several improvements in the diaphragm, and other details, and on two occasions read a paper respecting these improvements before the American Association for the Advancement of Science, and refer further, in this regard, to our back numbers, namely, page 120 of our May number, 1869; page 84, April number, 1877; and page 85, April number, 1878.

Dr. Cushman also expressed an opinion in regard to the success of the telephone companies now being organized in several localities in the United States as well as abroad. His opinion is so sound that we think no one will contest it. He says: "A good and useful application of the telephone, properly managed, if they start right, get arranged correctly, and do not undertake too much, will in practice be useful; but if they get confused in trying to use too many instruments upon one line, patrons will after a little become dissatisfied and lose confidence, and neglect to use the instrument, and the system will die out of use in time. On the other hand, if they are properly organized and trained, the instrument holders will succeed. However, time and experience will develop more upon the subject."

Manufacturer & Builder Jan 1880

THE EDISON LOUD-SPEAKING TELEPHONE.

The Birmingham Daily Post [illegible] 1879

Some interesting experiments were made yesterday in Birmingham with Mr. Edison's telephone. The instrument was fitted up at Messrs. Critchley and Co.'s show room in Cannon Street, and was connected with their works in the Coventry Road, about a mile and a half away. A long conversation was carried on through it; the voice of the speaker at the further end being most distinctly heard by several gentlemen standing in the Cannon Street room, at a considerable distance from the telephone. Directions as to details of work were given and repeated, fractional numbers were transmitted and were also repeated, in order to show that they were understood, and on closely approaching the instrument, even the faintest whisper was heard with perfect clearness. The general conversation was conducted in an ordinary tone, sometimes with rapidity of utterance, and now and then specially complex sentences were employed; in each variety of test the result was the same—the person stationed in the Coventry Road heard, understood, and answered what was said to him just as if he had been no further away than the other side of the room, instead of being a mile and a half distant. Had he been ten miles away, we are told, he would have heard and answered with equal facility. It is obvious that such a method of communication—simple, instantaneous, and free from liability to error—must be of great value to business men and others who desire to have unrestrained and immediate intercourse with those who are associated with them; and we are not surprised to learn that the Edison telephone is coming quickly into use in London and in some of the larger provincial towns. A company has been formed in London to work the invention, in connection with Mr. Edison; and branches, we understand, are being arranged in other places, including Birmingham. As the instrument now being shown in Cannon Street embodies the latest improvements made by Mr. Edison, an explanation of its principle and a description of its mechanism will not be unacceptable to our scientific readers. The scientific principles upon which the invention operates are entirely original with Mr. Edison. They are twofold, in that a different one is employed in the transmitter from that in use in the receiver. The transmitter operates upon the principle of varying the strength of a voltaic current, by the varying pressure of the sound waves upon a piece of carbon constituting a portion of the circuit, Mr. Edison having discovered that carbon had the property of varying its resistance to the passage of an electric current in proportion to the degree of pressure exerted upon it. This principle forms the basis of the telephone transmitter now in use by the telephone companies of America, and it was by virtue of it alone that the telephone there attained such wonderful commercial success, there being now upwards of 40,000 of them in practical use. The receiver—that is, the apparatus for reconverting the electric wave into sound—is based upon the principle of converting, by means of the electric current, a constant friction into a variable one. The *modus operandi*, which is exceedingly simple, may be thus described. A tympan, or diaphragm, of mica is held in position on the face of a vulcanite case, about four inches in diameter, being clamped firmly at its edges. Attached to the centre of this tympan and within the [illegible] metal about two inches long, standing [illegible] the tympan; the free end of this metal piece [illegible] upon a small cylinder of chemically prepared chalk, and is made to bear upon it with considerable pressure, by means of an india-rubber buffer placed immediately above. The chalk cylinder is rotated by means of a small crank which projects outside the case; when the cylinder is rotated the friction between it and the end of the metal bar is sufficient to force the tympan, to which the bar is attached, out of its true plane, or, in other words, to put it under tension somewhat analogous to a musical string. The electric waves, set free from the battery at the transmitting end by the action of the voice upon the carbon, and which therefore accurately represent the sound waves in their varying intensity, are made to pass through the metal bar and chalk cylinder, and effect in their passage at the point of friction a variation of the friction in the exact ratio of their intensity. It will thus be seen that the tympan is constantly endeavouring to regain its normal position, and succeeds in doing so only in proportion to the degree of neutralisation of the friction effected by the electric wave. That is to say, it is made to vibrate in harmony with the voice at the transmitting station, and consequently to contribute to the air at the receiving station precisely that form of motion given to that at the transmitting station, necessarily producing the same sound. The active principle, it will be seen, is the utilisation of the power of the hand at the receiving station to reinforce the electric current, thus permitting a much more decided vibration of the tympan than is possible in other telephones, since in them the electric current is compelled alone to perform the physical work of vibrating the tympan. The practical result of the device is the reproduction of the human voice at the distant station in something like its original compass, thus obviating the necessity for holding an instrument close to the ear. As we have already said, the means above described act perfectly: the distant speaker, if we did not know him to be far off, might be supposed to be actually close at hand. Every word comes full, clear, and distinct; the tone may be loud or low at pleasure; the utterance may be rapid or deliberate—every inflection and intonation of the speaker's voice is instantly reproduced, with such fidelity that the result constitutes a true miracle of science. Not only so, but the speaker may address a single auditor or an assembly at pleasure; he has but to raise his voice or to lower it, and the sound is either confined or diffused—the Edison telephone, the operators being miles away from each other, will faithfully convey a secret, a speech, or a song. We may add that Mr. Johnson, who is in attendance to explain the invention, and to show its wonderful capabilities, was an assistant of Mr. Edison, and that he will be glad to give illustrations and explanations to persons who are interested in the matter.

PROGRESS IN SCIENCE AND THE ARTS.

General Science. Engineering Journal

Edison's Electro-Chemical Telephone.—Mr. Edison is reported to have lately improved his carbon telephone so much that, in conjunction with a magnetic receiver, it far surpasses, for power and clearness of articulation, every other instrument thus far constructed. In the description of the apparatus just received, it is explained that, although the carbon telephone possessed points of superiority over other systems, its power was limited to the capabilities of the receiver with which it was connected; and until the present improvement had been perfected and applied, no receiving telephone had been introduced that would do justice to the capabilities of the carbon transmitter. The improvement referred to is described as consisting of the application of the principle of the "electro-motograph" (an earlier invention of Edison's) to the construction of a telephone receiver; and the result is affirmed to be a remarkable increase and improvement in the power and qualities of the instrument. It is said to be quite unnecessary to go near the instrument to hear messages, as they are delivered in a loud, clear tone, audible in any part of the room; indeed, it is declared to be difficult to distinguish any difference in distinctness of articulation between its utterances and those of a person engaged in conversation. A full description of this important improvement will be found in the last issue of the *Scientific American*, to which we refer our readers for details.

A New Acoustic Telephone.

American Inventor Dec 1879

Mr. E. D. Finch, of Stanton, Mich., has for some time experimented with acoustic telephones, and noted the faults connected with the ordinary string and diaphragm instruments sold so largely throughout the country. It is well known that in the use of the acoustic telephones, a great difficulty lies in the way of success from the fact that they can be used only a short distance, and even then in attaching them to short lines, the sounds emitted are so weak and indistinct, coupled with the fact that they change the sound of the voice beyond recognition, it might well be said that there is no successful acoustic instrument yet on the market. Mr. Finch, noting these defects, set to work with the view of securing, first, distinctness in the receiving instrument, and second, capacity for operating on long wires. As a result of this study he has shown us instruments of his make which differ from those heretofore made. The first object was to experiment in the direction of the size of the diaphragm. This he found to be most serviceable if made in size not to exceed six or seven inches in diameter; smaller than this produce poorer results. Next came the question of material; it was found, after repeated tests, that a silk or linen diaphragm answered the purpose to the best advantage. It was in the arrangement of this diaphragm that the greatest skill was required. The perfect instrument shows a linen diaphragm seven inches in diameter; stretched across this diaphragm are a number of wires radiating from the center and attached to the line at the central point of the diaphragm; these wires are on that side of the diaphragm nearest the operator. The object of the radiating wires, as explained by Mr. Finch, are, first, to give strength to the line wire in its connection, and secondly, to absorb more of the sound waves of the voice and communicate the same to the line wire. Two of these instruments have been tested here under our supervision, and we find that they work admirably in every respect.

EDISON'S LATEST TELEPHONE.

Oct 15 [illegible] 79

Since the first appearance of Professor Edison's electro-chemical telephone it has passed through a succession of changes until it has finally assumed the compact and convenient form shown in the accompanying engraving. The form, however, is not the only change. In the first electro-chemical telephone, it will be remembered, the chalk cylinder was supplied with moisture by a movable roller which dipped in the exciting fluid and supplied it with moisture. This movable roller is now dispensed with, and the chalk cylinder is enclosed in a vulcanite box, seen at the end of the movable arm. The cylinder, when once moistened, remains in that condition for an indefinite period, as the box is practically air-tight.

The small shaft that runs parallel with the iron arm extends through the side of the box and carries the chalk cylinder. Upon the opposite end there is a small pinion moved by a worm, the crank of which is turned by the finger. The diaphragm of the receiving instrument is covered by the front of the box, excepting a small central portion which is quite sufficient for the exit of the sound.

The arm which supports the receiving instrument is jointed so that it may be raised vertically out of the way when the telephone is not in use.

The transmitter, fig. 1, is contained in the stationary rectangular box; its mouthpiece projects slightly, and the diaphragm, which is of mica, is supported by a metal frame and springs inside the box cover. This transmitter is quite different from the carbon transmitters now so largely in use in America, and it will be new to many of our readers; but it is one

Theory of the Microphone.—Prof. Julian Ochorowicz considers the chief causes of the action of all possible forms of microphone to be a mechanical movement of its parts, a change in the points of conductivity, and a change of resistance—three essentials which result from one another. He holds that there is no increase of sound by the microphone, as usually understood. All sounds are weakened by the microphone, and are transmitted only when the source of sound is in direct contact with the microphone or its stand. The microphone is less an instrument for transmitting sound than for transforming mechanical movement into sound. The intensity of a sound is, therefore, directly proportional to the energy of the mechanical movement accompanying the sonorous waves, or, as a necessary consequence, to the changes of resistance in the microphone. The distinctness of articulate sounds transmitted by the microphone is in inverse proportion to their intensity; for a loud sound tends to interrupt the current completely, and thus to prevent the transmission of articulate sounds. This is the chief hindrance to increasing at pleasure the loudness of the sound. The loudness of the sound is also dependent on the strength of the current. Electrician Oct 11 1879

The Audiphone.

Jan 1880

Several exhibitions have been given of late showing how much deaf and dumb persons may be assisted in hearing by the use of an instrument called the Audiphone, by which sound is conveyed through the medium of the teeth and auditory nerve. The inventor of the audiphone is Mr. Richard S. Rhodes, of Chicago, who is very deaf. The instrument was suggested to him about two years ago, by the discovery that on placing his watch against his teeth he could distinctly hear its ticking, though unable to do so upon the usual application to the ear. After a year's work he perfected the instrument. It closely resembles a black fan; it consists essentially of a diaphragm of hard rubber, very thin and elastic, about a foot square, with rounding corners and a neat hard-rubber handle. When in use a silken cord draws down on the inside the top of the diaphragm, presenting a convex surface to the speaker. In this position the upper edge is pressed firmly against the interior edge of the upper teeth, and the sound falling upon this surface is conveyed to the auditory nerve.

At a recent exhibition in Philadelphia, a young man seventeen years old, who has been deaf since he was nine years old, but who could answer vocally questions asked by the sign language, was brought forward. When the audiphone was adjusted to his teeth, Mr. Rhodes asked his name in a loud voice. The boy evidently reaped a new experience, for his face lighted up with a smile. "I heard it, but I don't know what it was," he said.

At Hartford, Conn., two ladies sang a duet, with piano accompaniment, before the children in the Deaf and Dumb Asylum, and the children, on being asked how many heard it, three-fourths of them raised their hands; but upon being questioned, they generally asserted that they heard the piano, but could not hear the voices. The "laughing song" manifestly pleased some of the children.

[38150.]—**Telegraph or Telephone.**—The telephone is a very handy instrument for communicating over such distances as three miles or so. More so, even than the "A B C" instrument, as any person can use it that can speak and hear. It simply consists of a switch-board at each end of line-wire, with a call-bell fixed to each, and a battery for ringing same, and, when rung, the person present approaches telephone, which is resting on switch-holder, and the act of raising telephone to speak or hear throws batteries and bells out of circuit, and puts itself in; communication can be carried on as distinctly as if the person spoke through a speaking-tube 100 feet long. The probable cost of laying line-wire would run about £10 to £16 per mile, according to locality.—G. W., Liverpool. English Mechanic Nov 14

[38150.]—**Telegraph or Telephone.**—In your case I should recommend to employ A. B. C. telegraph instruments.—T. Wiesenbonger.

[38150.]—**Telegraph or Telephone.**—"Wanderer's" best plan would be to get a good reliable work on the construction and maintenance of telegraphs; that would probably give him all the information he desires. A very good work of the sort is one by Preece and Sivewright, "Text-Books of Science—Telegraphy"; but "Wanderer" may know of even better. I can safely say it would cost a good round sum, 18 poles to the mile being the lowest possible estimate, and 15s., or so a pole, insulators, wire, and cost of putting up the line, and a battery-power of 10 Daniells cells. A telephone would be by far the better mode of conversing; cheaper too; but it would be a great expense for one man to bear, and perhaps not satisfactory after all.—W. A. Y.

[38150.]—**Telegraph or Telephone.**—For so short a distance the telephone would work well, and, being the easiest for every one to work, would, I should think, be the most useful to you. You could, I believe, by an annual payment, have a wire from the office to your house. Get the "Postal Guide" (6d.), and you will find all the information you require as to fixing and rental of wire and instruments.—W. J. Lancaster.

Another Audiphone.

Dec 1879

The audiphone, as constructed by Professor Graydon, consists of a small electro-microphone, in the center of the diaphragm of which is attached a cord, which may be of any length, and to the other end of which cord is attached a small piece of wood. The manner of working the instrument is simple, and can be briefly described as follows. The deaf person takes a firm hold of the piece of wood between his upper and lower teeth, and the party desiring to converse with the deaf talks through the electro-microphone attachment at the other end of the cord, holding the cord taut. The theory advanced is that the sound is conveyed through the nerves of the teeth and the bones of the face to the auditory nerve, which, owing to some defection of the ear caused by disease is not approachable through the usual channel, thence to the brain. The instrument will only work, however, when deafness has been caused by disease. In case of paralysis of the auditory nerve it is useless. Some very interesting tests of the audiphone were made at the deaf and dumb department attached to the Third Intermediate School recently. Among others was one, a bright looking colored girl, who was entirely deaf. The professor talked to her at a distance of twenty-five feet through the instrument, and she repeated after him every thing which he said. Another was a little girl who had been deaf and dumb from birth. Using the mute alphabet she informed the teacher in charge that she could hear that one statement of the professor was made in a louder tone of voice than another, but that she could not understand what he said, never having been able to hear such sounds before. In some other cases, however, the pupils upon whom the instrument was tried said, in their mute language, that they were unable to distinguish any sound whatever. It is fair to presume that the instrument will, as have the telephone and microphone, be greatly improved, and that at no distant day it will be of great service to those afflicted by deafness.—*Cin. Gazette.*

A MICROPHONE FOR THE TRANSMISSION OF MUSICAL SOUNDS.

[16290.]—In attempting to transmit musical sounds by the microphone, it is usually found that the sound emitted by the telephone has degenerated to a hoarse rattle, caused by the jarring of the movable part of the microphone. By reducing the play of the lever, or upright piece, this disagreeable effect may be diminished, but only at the expense of the sensibility of the instrument, which is then mute to the higher and softer notes.

The form of microphone described below is free from these objections, and, so far as I can tell, it transmits every musical sound, high or low, absolutely pure and unchanged. It may therefore be found useful for the accurate study of the sounds emitted by the diaphragm of the telephone. It consists of a deal box of a cubical form, about a foot high. It is open at the back and has a circular aperture in the front. A piece of guttapercha tissue is tightly strained over a wooden ring and fixed upon the aperture. In the centre of this diaphragm a small block of carbon is fixed connected by a fine wire with the binding screw at A. At B is another binding screw, and from it proceeds a light steel spring tipped with carbon, and bearing

Eng Mechanic

Oct 10 1879

with very gentle pressure upon the carbon-block at C. The pressure of the spring can be regulated by any suitable means. Perhaps the simplest way is to take a stiff brass wire, bend it at right angles and pass one end through a hole in the box at D, in which it slides stiffly. Its other end can then be made to bear with any required pressure upon the end of the steel spring. W. H. Snell.

Bampton-street, Tiverton.

[38306.]—**Blake's Patent Transmitter.**—This is a kind of microphone. It has an ordinary ferrotype plate diaphragm; pressing slightly in the centre is a small ball of platinum or other metal. It is about 1-16th of an inch in diameter, and is held in the middle by a spring. It looks like a small lead shot being forced half-way through a piece of steel spring. On the opposite side of the shot or ball is a carbon button. These are connected to the primary of an induction coil and a one-cell Leclanché. The secondary wire is of course connected to line and earth, to which are attached ordinary Bell telephones; it makes the latter instrument perfect. For instance, a gentleman whistled an air 60ft. from the Blake's transmitter, then suddenly left off, and his son, 14 mile distance, immediately took that part up, and there were about 60 persons in the room, and they all heard the whistling quite plain, while I held a pair of Bell telephones in my hands. Singing could also be heard all over the room, and the tune distinguished but not the words.—George Tolman. Eng Mec

On the Retardation of Phase of Vibrations transmitted by the Telephone.

By Professor S. P. THOMPSON.

Dubois-Reymond predicted from theoretical considerations that a difference of phase, amounting to a quarter of a complete vibration, would be found to exist between the diaphragms of two Bell telephones, joined up in one circuit, the receiving telephone being a quarter of a vibration behind the transmitter. Helmholtz and Weber theoretically predicted only a small difference of phase. Recently König in a series of delicate experiments, effected an optical comparison by the method of Lissajous, of the vibrations of a pair of telephones, replacing the vibrating discs by tuning-forks armed with mirrors. The author has proposed the following method of observing. A pair of Bell telephones are suspended by wires of about a metre in length, so as to oscillate as pendulums, to frames so disposed as to avoid the possibility of any mechanical transmission of the vibrations. Below the point of rest of each telephone, and at some little distance from it in the plane of its swinging, is placed a steel magnet. After the lengths of the wires have been so adjusted that the telephones will swing in identical periods, one telephone is set swinging. As it alternately approaches and recedes from the magnet, the induced currents traversing the second telephone set it swinging. In every case the difference of phase observed amounted to one quarter.

In the case of those telephones which transmit vibrations by varying the resistance of the circuit, instead of varying the electro-motive force, there is no such retardation of phase produced in the ordinary electro-magnetic receiver. If, however, the current so transmitted is first passed through an induction coil, a retardation of phase of one quarter is produced, and in the case of several successive inductions the retardation amounts to an additional quarter for every additional induction. This remark applies only to vibrations of harmonic and quasi-harmonic type.

In the case of Edison's motographic or electro-chemical receiver, the velocities, not the displacement of the disc, are proportional to the strength of the currents received. Hence vibrations already retarded one quarter in transmission, as is the case with those of the carbon transmitter in conjunction with its induction coil, always used with this instrument, are restored to their primitive phase. The vibrations of this receiver therefore agree with those corresponding to the function of which the vibrations of the induction current are the derivate; that is to say, they agree in type with the primitive vibrations of whatever form. In the receiving telephone of Edison, therefore, consonantal sounds which depart widely from the purely harmonic type are better rendered than in a telephone which like that of Bell both retards the vibrations in phase and alters them in type. Tele. Jour. Sep. 15/79

The Battle of the Telephone Companies.—The Edison Telephone Company, fortified by the disclaimer to Edison's telephone patents, have stopped the India-rubber, Gutta Percha, and Telegraph Works Company (Limited) from making the Blake transmitter for the Telephone Company (Bell's). The Edison Company holds that transmitter to be an infringement of their patents, and they are determined to take steps against any other company making these transmitters. There is no especial merit in the Blake transmitter that its disuse should seriously inconvenience the Bell Company, since Crossley's or any other good microphone will answer just as well.

Telephony in Glasgow.—The extended use of the telephone for commercial purposes has been provided for in Glasgow by the establishment of two companies, the Edison Telephone Company (Limited) and the Telephone Company (Limited), the former having its central offices in Royal Exchange Square, and the latter having temporary offices at 72, Queen Street. The Edison Company employ the Edison Loud-Speaking Telephone, while the other company use their own improved telephone. It is intended to form telephonic circuits, comprising places of business in and around the city, by means of which the various patrons of the companies will be brought into direct communication with the central stations, and with each other

REVUE DES TRAVAUX

RÉCENTS EN ÉLECTRICITÉ

Nov 1879

Sous cette rubrique nous indiquerons désormais dans chacun nos numéros, ce qui s'est fait d'intéressant en électricité dans la quinzaine.

Nouveau Téléphone de M. Edison.

Dans notre article du 15 mai sur les dernières découvertes en téléphonie, nous avons parlé du système de téléphone électro-chimique de M. Edison, lequel n'était qu'une modification de celui qu'il avait imaginé dès l'année 1877, et qui est décrit dans l'ouvrage sur le téléphone de M. du Moncel. Dans ce nouvel appareil, fondé sur le principe de l'*électro-motographe*, un cylindre de chaux se trouvait substitué à la bande de papier; mais il fallait qu'il fût entretenu dans un certain état d'humidité qui n'était pas facile à obtenir d'une manière régulière. Dans le nouveau modèle, ce cylindre de chaux *peut rester sec*, ce qui est évidemment un avantage pratique. Mais, ce qui a été le plus modifié, c'est le transmetteur, que le *Telegraphic Journal* décrit de la manière suivante: « Le transmetteur est contenu dans une boîte rectangulaire fixée contre un mur, et son embouchure n'a qu'une légère saillie. Le diaphragme est en mica et supporté par un cadre et un ressort métalliques placés à l'intérieur du couvercle de la boîte. Au centre de ce diaphragme est fixée, par un écrou métallique mis en communication avec l'un des pôles de la batterie, une petite équerre d'ébonite qui est creusée, devant l'écrou, de manière à former une cavité dans laquelle est introduit un bout de crayon de charbon à lumière électrique, arrondi par ses extrémités, et sur lequel appuie extérieurement un ressort de platine fixé au bout de l'équerre d'ébonite. A l'extrémité de ce ressort, sur la partie correspondante au point de contact, est *fixée une masse métallique pesante*, et la pression du ressort est réglée par une vis de réglage. Un fil conducteur adapté à ce ressort complète le circuit qui, comme dans les autres systèmes d'Edison, correspond au circuit primaire de la bobine d'induction appelée à réagir sur le circuit du récepteur. Celui-ci se trouve, en plus, relié à une troisième hélice qui enveloppe l'hélice secondaire de cette bobine, et c'est le courant ainsi renforcé qui traverse le cylindre de chaux du récepteur. Sous la boîte du transmetteur se trouvent deux clefs, l'une qui sert à envoyer des signaux Morse, comme dans son premier système, l'autre qu'on presse au moment de la réception de la dépêche et qui sert de commutateur. »

Ce système de transmetteur n'est, par le fait, qu'un microphone semblable à beaucoup de ceux qui ont été déjà décrits, auquel on a ajouté *la masse métallique* qui a produit de si étonnants effets dans les expériences de M. Ader. Il est vrai que ce dernier n'avait employé la masse pesante que pour le récepteur, mais il pourrait bien se faire que les effets avantageux que cette masse produit, puissent s'appliquer à la transmission comme à la réception.

Pour obtenir la suppression de l'humidification du cylindre de chaux, M. Edison emploie de la chaux solidifiée à une *grande pression*, et imprégnée d'une solution de phosphate de soude hydrogéné (*hydrogen disodic phosphate*). Il faut que la solution employée soit alcaline, et, suivant lui, un phosphate alcalin, tel que le phosphate de soude, est ce qu'il y a de mieux.

Le récepteur, du reste, qui est maintenant de trop petites dimensions, est fixé à l'extrémité d'un bras adapté perpendiculairement à la boîte du transmetteur, et se trouve relié à la manivelle destinée à faire tourner le cylindre de chaux au moyen d'une tige d'engrenage. Par cette disposition, le récepteur s'adapte naturellement à l'oreille de celui qui place sa tête contre le transmetteur pour parler.

Expériences nouvelles sur la théorie du Téléphone

M. Percival Jenns, recteur de Saint-Jean dans la Colombie anglaise, a envoyé au journal *Nature* un résumé des expériences qu'il a entreprises pour reconnaître l'origine des sons dans le téléphone

---

des phases de leur composition. Les vibrations des consonnes, au contraire, se distinguent mieux, car elles se séparent de plus en plus du type primitif, à chaque succession des actions d'induction.

« Dans le cas du motographe d'Edison, c'est-à-dire de son récepteur électro-chimique, la vitesse du déplacement du disque est proportionnelle à la force du courant reçu, et, par conséquent, les vibrations déjà retardées d'un quart de transmission, comme c'est le cas dans les transmetteurs à charbon réunis à des bobines d'induction (employées toujours avec cet instrument), reviennent à leur état normal. Les vibrations de ce récepteur sont donc du même type, non comme vibrations du courant induit (qui correspondent aux fonctions dérivées des vibrations primitives), mais comme vibrations correspondantes aux fonctions dont les vibrations du courant d'induction sont les dérivées; ce qui veut dire qu'elles s'accordent, comme type, avec les vibrations primitives de n'importe quelle forme d'appareils. Par exemple, dans le téléphone récepteur d'Edison, les sons des consonnes qui sont émises avec force et qui appartiennent au type harmonique, sont mieux rendues que par un téléphone qui, comme ceux de M. Bell, retarde la phase des vibrations et altère leur type. »

2407. TRANSMITTERS FOR TELEPHONES, *A. Marr.—Dated 21st June, 1879.* 6d.

The diaphragms are made of wood, and inside and near the centre are attached discs of solid carbon placed close to each other and connected respectively with the opposite poles of a voltaic battery or a magnetic current; the receiving telephone being in the circuit. The outer edges of the diaphragms are joined together by an angular piece of wood, and the space between, about ⅛in.—the carbon discs being about ⅛in. apart—is filled with powdered carbon. The Engineer [illegible]

Mining & Sci Press March 6, 1880.

Are Telephones Telegraphs?

A somewhat singular discussion, involving the question as to whether telephones are telegraphs, has arisen in England, growing out of the fact of the connection of the Postoffice Department there with the telegraph. An application has been made for an injunction against the Telephone company to restrain them from discharging their functions, except under the Postoffice regulation in relation to the telegraph. After some considerable discussion it has been arranged that an injunction should not be taken, but that the defendant companies were to keep certain accounts until the hearing and final decision of the case.

The argument on behalf of the Postoffice is that telephones are telegraphs within the meaning of the act by which the latter inventions were committed to the charge of the Postoffice Department, and the Attorney-General represented it to be a serious grievance that the government, after spending millions on telegraphs, now found their monopoly interfered with by telephones, which, he submitted, were practically the same invention. The government had, therefore, he said, begun these proceedings by information in the Court of Exchequer.

It is reported, although this part of the question was not mentioned during the hearing, that they hope to be able to compel the telephone companies to take out licenses from the Postmaster-General, and pay royalties for doing so. The *Times* has an editorial on this subject, which concludes as follows: "The proposal to obstruct the development of the invention is one it would be impossible to defend. The fiscal argument is simply irrelevant. If the nation made a bad bargain in forgetfulness of the admitted commercial principle that few patents are worth more than three years' purchase of the receipts arising from them, the nation must bear the loss, however great it may be. It will not be diminished otherwise than apparently, by restricting the use of telephones. If any such restriction is sanctioned by the courts, it can scarcely fail to be removed by the direct intervention of the legislature. A tax upon telephones would be practically a tax upon knowledge. Any such imposts belong to the past rather than to the present or future."

19

Practical American Nov 1879

The Telephone to be Prohibited in England.

THE English Government is about to take measures practically equivalent to a prohibition of the telephone, or which at least will put a powerful check upon the extension of its use. There are no telegraph companies there, but the whole telegraphic business is under the sole government control, and combined with the post-office, while at every post-office there is a telegraph office also. The Post-office administration has found that the extension of the use of the telephone considerably decreases the revenues of their business, because when people can talk over the wire they don't want to send expensive telegrams or letters, with long delayed answers, and it has become a legal question if not the telephone is an infringement upon the government privilege of transmitting telegrams as well as letters.

We wonder if the British Government will give an example to the world of taking measures equivalent to a practical prohibition of one of the most important inventions of modern times, and do that in a country which boasts of its enlightenment and progressive tendencies.

P. S.—The above was written after a cable dispatch brought the news; since then the mail brought the papers, among them the London *Times*, which expresses opinions about it identical with those expressed by us.

Il serait difficile, écrit au *Times*, le directeur de la Compagnie des téléphones Edison, de donner une idée plus frappante des résultats que l'on peut obtenir avec le téléphone Edison que la simple citation du fait suivant. Le 8 novembre un monsieur, dont la maison avait été mise en communication avec le bureau d'échange des téléphones Edison, était allé en partie de chasse. Au moment de son départ le téléphone n'avait pas été fixé, bien que le fil eût été posé. Pendant son absence ce travail fut accompli et à son retour des lettres importantes lui furent lues, lettres auxquelles il dicta des réponses. Une conversation avec ses hommes d'affaires étant nécessaire, l'opérateur du bureau central établit une communication. Un important télégramme de New-York fut reçu et une réponse fut dictée assez à temps pour arriver à New-York trois heures après l'envoi d'Amérique du premier message. La plus grande partie du travail d'une journée en ville fut ainsi achevée en une demi-heure dans une bibliothèque.

Electrician Week 2/7/1880

THE CHALK CYLINDER BATTERY.—Professor Barrett writes:—"When I sent my note to the Physical Society, announcing the production of an electric current by the friction of metal on a revolving chalk cylinder (the only case I know where friction, or, at any rate, the relative motion of two dissimilar conductors in contact, generates a continuous electric current), I was unaware that Mr. Edison had already made a similar discovery. I was first informed of the fact by Mr. Johnson, the electrician to the London Telephone Company. Although I see *The Electrician*, in common with most of the other English journals, every week, the announcement of Edison's discovery escaped me, and I should be glad if you would refer me to its record in your columns or elsewhere, and I will take care to make an immediate disclaimer in the matter." [Professor Barrett then, with some justice, goes on to comment on the remarks in our Note of last week. If we say this, we need say no more on the subject.—ED. *E.*]

Scrap book

THE EDISON TELEPHONE IN BOLTON.

Reprinted from the "Bolton Evening News," March 10th, 1880.

Since we had the pleasure of seeing and hearing the telephone at the offices of the Edison Telephone Company, in Exchange-street, the Company have considerably extended their operations, running wires to various places of business in the town, and have opened the telephonic exchange, both locally and in connection with the one in Manchester, thus enabling their subscribers to talk from their own counting-houses with those of their friends in Manchester. Before describing the ingenious manner in which this is accomplished, it may interest our readers if we describe the telephone as perfected by Mr. Edison, which we are able to do by the courtesy of Mr. G. W. Benson, the district manager. The transmitter, or speaking portion of the instrument, is made of carbon, which is obtained from the smoke of paraffin lamps. This is moulded into a circular form and placed between two metal discs of about three-fourths of an inch in diameter; these are fixed in the centre of a ring of vulcanite, and the whole is embedded in and surrounded by a circular iron case of three inches diameter. On the centre of the iron diaphragm is fixed a short tube of brass, which holds within it a projecting length of glass tubing; this and the screw opposite to it from the outside of the transmitter, press against the metal discs. To enable the voice to be directed against the centre of the discs, a mouthpiece is attached, into which the operator speaks, thus overcoming the defect in the "Blake transmitter," where the voice has to be some distance off and spoken in a loud tone, and thereby can not only be heard all over the room, but is liable to transmit other sounds and conversation. From the Edison transmitter a low, soft voice is heard with perfect distinctness, and, in fact, we are informed, the difficulty with new subscribers is that they speak too loud. The receiving portion of the instrument is, however, the distinguishing feature in the Edison telephone. The general one hitherto in use has been a magneto one, and to hear the voice needs pressing close to the ear, but the sound is so faint that it is not easy to hear, unless there is comparative stillness in the room, and when the wires are troubled by induction it is almost inaudible. To overcome these objections, Mr. Edison, after long and patent investigation and experiments, brought out his electric monograph receiver. Briefly described it consists of a cylinder of chalk about the size of a small cotton reel, which is mounted upon a spindle capable of being rotated by a small handle. Attached to the centre of a disc of mica is a brass strip faced with platinum, which projects over the chalk cylinder, and is made to press upon it by means of an India-rubber spring. The wires are so attached that the electric current is made to pass from strip to and through the cylinder at the point of contact. Upon turning the handle so as to rotate the cylinder outwards from the face of the disc, the friction between the cylinder and the strip draws the centre of the disc inwards, giving it a curved face. If an impulse of electricity be passed over the wire, the friction between the strip and the cylinder is destroyed and the disc regains its normal position. If a variable or undulatory current of electricity be transmitted through the instrument, the diaphragm is kept in continual motion by the constantly varying friction existing between the chalk and the platinum, dragging the diaphragm in opposition to its own elastic tension. So sensitive is this arrangement, that all the undulations produced by the human voice instantly produce their corresponding variations of frictional resistance, and the diaphragm reproduces, in a loud or magnified tone, words or sounds which are being uttered into the telephone at the other end of the wire, whether in a loud or soft tone, a whisper, or even a breath, so that although the Edison telephone is called loud speaking it is none the less soft speaking also. When the subscriber at a distant station in Manchester was asked to speak in his usual tone of voice, the words uttered were heard in the office in Bolton above the hum of conversation a few yards from the instrument, when, in a low tone, only a muttering was perceptible to the bystander though perfectly audible to the person listening at the instrument. At the top of the company's premises is the switch room into which the wires are brought from the various subscribers' offices and mills, and from the Manchester Exchange. Each switch board serves for 24 different stations, which is as many as one person can attend to at one time; but other boards will be added as required, and there may be any number of those in connection, so that any station on one board can be connected with any other station on another board. The board is a beautiful piece of mechanism, consisting of 24 brass strips, crossed by others at right angles; above are the indicators or shutters. Adjoining the switch board is the telephone for the use of the attendant, who sits in front of the board. Assuming that subscriber No. 5 wants to speak to No. 4, the person at No. 5 calls attention to the attendant at the Exchange by ringing his bell, and a shutter drops simultaneously disclosing his number. The attendant then inserts a brass pin into the switch board and thus connects his instrument with that of No. 5, who answers, "Connect me with No. 4." The attendant shifts the pin into a vacant portion of the switch board, and places No. 4's pin on the same line, and the two are then in direct communication. When they have finished talking they ring their bells and the shutters drop, the pins are withdrawn and they are disconnected. Thus subscribers can be instantly connected and disconnected, and any number can be connected up in couples, and be talking at the same time. If a subscriber wants to talk to a Manchester subscriber the operation is similar. For instance, No. 5, having finished with No. 4, wishes to talk to his Manchester warehouse which, in this case, is No. 3 on the Manchester Board. He has merely to ask for No. 1, *i.e.*, the Manchester Exchange, and on receiving a reply from there says, "Connect me with No. 3," and the two are in direct communication, although 15 miles apart, and talking through two switch boards. The whole is as simple as ingenious. Ease, rapidity, certainty, and privacy, are the great advantages of this system. A telegraphic message is wanting on these points, as it needs writing out, and perhaps in a way which cannot convey the exact meaning; sending to the office; transmitting by a skilled operator, interpreted often incorrectly, written out again, and then conveyed by a messenger to the abode or place of business of the receiver; opened and read, and passing under the eyes of at least two strangers; whilst in the new form of communication one person speaks to another as if in the same room, and receives his reply at once; and, if necessary, in perfect secrecy. The utility of this mode of communication is boundless. Gentlemen in business, who live out of town, can have their letters read to them from their offices, and dictate the replies or speak to a customer without leaving the breakfast room. The legal and medical professions will find it a great economy of time and money, consultations may be arranged or even take place at once between themselves and their clients, and a doctor in case of accidents can give directions before arriving at the house. Besides business and professional men, the various public offices, hotels, and livery stable keepers, and the main tradesmen will find it necessary to be connected with the exchange, for by its means our wives will order their household commodities, send for a cab, and learn it is *en route*, and will be able in a few minutes to arrange picnic, riding, musical, or even dinner parties. Mr. Benson tells us that some of the Manchester subscribers have informed him it paid for itself in one month.

OVER

THE CHALK CYLINDER BATTERY.—Professor Barrett writes:—"When I sent my note to the Physical Society, announcing the production of an electric current by the friction of metal on a revolving chalk cylinder (the only case I know where friction, or, at any rate, the relative motion of two dissimilar conductors in contact, generates a continuous electric current), I was unaware that Mr. Edison had already made a similar discovery. I was first informed of the fact by Mr. Johnson, the electrician to the London Telephone Company. Although I see *The Electrician*, in common with most of the other English journals, every week, the announcement of Edison's discovery escaped me, and I should be glad if you would refer me to its record in your columns or elsewhere, and I will take care to make an immediate disclaimer in the matter." [Professor Barrett then, with some justice, goes on to comment on the remarks in our Note of last week. If we say this, we need say no more on the subject.—ED. E.]

5009. FRICTION TELEPHONES OR ELECTRO-MOTOGRAPHS. *J. Imray.*—(*A communication.*)—(*Complete.*) 6d. *Dated 6th December, 1879.*—A cylinder of compressed chalk is soaked in an electrolytic solution, such as caustic alkali, to give conductivity. The axis of the cylinder is connected by gearing to an axis with a handle, by turning which the cylinder is rotated. On the periphery of the cylinder a blade attached to the diaphragm is pressed by a piece of wire acted on by a spring. The line wire is attached to the blade and the axis of the cylinder is connected to the earth. A pivotted lever carries a roller at one end which dips into a water reservoir, and the other end of the lever can be moved downwards, so as to raise the roller in contact with the cylinder and so moisten the latter.

May 15 1880

THE TELEPHONE.

"EDISON" AND "BELL."

THERE are, among the multitude of sages who can be wise after events, many who see in Puck's boast, "I put a girdle round about the earth in forty minutes," a fore-telling of telegraphic wonders by Shakespeare. In like manner, before common use shall drill the general mind as to the marvels of the telephone, now coming very rapidly into use in London, and England generally, there may be found among the crowd who cloak their inability to comprehend the greatness of modern inventions by the formula, "There is nothing new under the sun," some who will trace in the summoned "Genie of the Lamp" and "Genie of the Ring" a proof that the Easterns understood the possibility of communicating over unknown distances by unknown and mysterious influences. It may be argued, indeed, and with some show of force, that "carbon" in the form of jewels was very largely associated with Aladdin's experiments, and that the truth in the bygone dream of the telephone in the "Arabian Nights' Entertainments" is proved by the received maxim that dreams go by the principle of reversion, for, while the carbonised jewels were "transmitted" to Aladdin, the carbon in its duller form is the transmitter—or, rather, a principal agent in the modern invention.

Leaving, however, these dreams and speculations for the idle and careless, we come to the great fact that to-day we have in London, in practical use, two systems of telephonic communication, and it has been our business to practically examine both the "Edison" and "Bell," with the view of laying the particulars before our readers, so as to enable them to judge of the advantages which this new system of communication has over all others. These advantages are manifold and self-evident, the first being that it enables principals in business to communicate *at once*, without the intervention of subordinates, and to learn at once, without the difficulties and delays of writing, the thoughts which they may desire to exchange. For instance, at present the editor of the daily paper, sitting in his office in London, in the discharge of his duty to the public, has to direct the "leaders" for the morrow's paper, and he can only do this on ascertained facts. These facts are transpiring in the Houses of Parliament two miles distant by carriage. The editor has the utmost need for consulting his chief of the staff at "the Houses" direct; but he can only do so by an immense loss of his valuable time in driving to the Houses, and in dashing through the labyrinths of the vast building. The "fierce heat" which beats about the daily newspaper press—that is to say, the stern necessity which exists for holding in the utmost secrecy the views which may be contained in the morrow's leader—compels the editor to throw aside the use of the telegraph in this case, for the use of the telegraph would require that he should open his mind clearly and distinctly to a mechanical subordinate, whose receptive faculties, perhaps, might be unequal to convey and reconvey the delicate touches which play about a political "policy." The telegraph has been and is a wonderful help; but it is not everything. Even where it is "laid on," as in newspaper offices, the clerks are the father confessors of their employers, and if they go out for "a smoke" in the intervals of work they may prematurely "let out" important facts where the unholy band of "London correspondents" to country papers most do congregate, and "London correspondents," by placing the country newspapers on a level with the town productions in the matter of into news, make themselves the deadliest enemy the London newspaper proprietor has to contend with. It is thus easy to be seen in what respects the London newspaper editor has for keeping to himself his "exchanges" of communications. As a contrast to the clumsy system of writing, or going in person to "the Houses," the editor can open his telephone and hold his direct communication—a system which, speaking from practical experience of daily newspaper work, we can say will lighten the labours of an editor of a daily newspaper, will lessen the "harass," and will keep his office secrets perfectly free from the dangers of "tapping." Then the counsel engaged in a case at Westminster will be able to be placed in communication with his solicitor at Chancery-lane; and law, if not justice, will be facilitated by the immediate personal communications between those who are watching and directing the same interests from different points. The merchant, in his counting-house, keenly sensible to all the ramifications of a vast business, will, by means of the telephone, have his affairs under the operation of his own eye. He will not need a correspondence to the great extent he is at present compelled upon to enter. The merchant class will, under the new system, be placed in direct and instant communication with those with whom they do business, and the wonderful change which will thus be wrought can only be foreseen by those who can take the trouble to "think out" the results which will follow on placing the ears and voices of the most important members of our busy community in instant and complete relation. To insurance offices the telephonic communications are clearly a necessity of which they must avail themselves.

We "wanted to know" all about the "Edison," and we travelled to the head-office, at 11, Queen Victoria-street, E.C. We found there a busy convocation of gentlemen, and the introductions were so rapidly performed that we can only guess, respecting the gentlemen we first saw, that they were Mr. Arnold White and Colonel Godfrey Twiss, the secretary and assistant-secretary of the Edison Telephone Company of London, Limited. We have no doubt about the next introduction, which was to Mr. E. H. Johnson, the chief engineer, a gentleman, we soon found, whose reverence for that high priest of practical invention, Mr. Edison, was only equalled by a knowledge of the instrument now being brought into working. We were "rushed," so to speak, from one apartment to another for our guide, philosopher, and friend on the occasion, while exhibiting that remarkable characteristic courtesy which is an importation from America, and contrasts so distinctly with general British brusqueness, was unmistakably in haste. It was evident that orders for telephonic communication were tumbling in, and that Mr. Johnson's mind was literally being wired at from at least a hundred different centres; so it is not surprising that his speech, like the Mary May of Hood's "Copper in the Air," should have been "full trotting," as if he had, like the interesting damsel after Mrs. Round's experiment in explosives, too much to tell before his death.

Mr. Johnson placed us before an Edison telephone, which, he stated, was in communication with various circuits, and one point of communication was at Norwood, over fifteen miles of wire. He drew our attention to the peculiarities of the instrument—in that the speaker through it, by the Edison system, is in direct contact with the two distinct parts—the "transmitter" and the "receiver"—the one transmitting the message from the speaker's lips, the other receiving the return message and pouring it into his ears, and, as it is, loud speaking, into the room where the instrument stands. The whole space occupied by the instrument, we may mention, *en passant*, is about that which would be occupied by one's hat upon the wall. Mr. Johnson explained to us the mechanical arrangements of the telephone, and he illustrated the action of the voice upon wires by drawing a straight line upon the wall, and thus described the voice as passing in waves over it after being received by the transmitter upon the diaphragm, and acted upon by Mr. Edison's carbon points and metallic discs. The "receiver" is conveniently close to the ear while the speaker talks into the telephone, and, in the space of the penny bun of commerce, contains Mr. Edison's special invention for the enlargement of the tone received. The receiver of the message turns a little cranked handle with his right hand, and this may turn to the right or to the left, or be changed in the circuit it may take, without causing any breakage or loss of message. The receiver has a diaphragm upon which the received message falls and is conveyed to the ear. Mr. Edison's latest improvement up to date is to place a cylinder of pure chalk, mounted upon a spindle, which is rotated by the cranked handle. Attached to the diaphragm, which is a disc of mica, is a brass strip faced with platinum, which projects over the cylinder, and is made to press upon it by means of a spring. The wires are so attached that the electric current is made to pass from the brass strip to and through the chalk cylinder at the point of contact—a point which is also the point of friction. When the handle is turned the cylinder is rotated outwards from the face of the disc, and the friction between the cylinder and the strip draws the centre of the disc of mica inwards, giving it a curved face. When an impulse of electricity is passed down the wire the friction between the strip and the cylinder is destroyed, and the disc regains its normal position of a true plane. When a variable or undulatory current of electricity is transmitted through the instrument, the diaphragm is kept in continual motion by the constantly-varying friction existing between the cylinder of chalk and the platinum, dragging the diaphragm in opposition to its own constant elastic tension. The simple mechanical arrangement thus presented is exceedingly sensitive to the smallest, as well as to the most rapid, of complicated variations in electrical intensity occurring in the transmitted current. It is so sensitive, indeed, that all the complex undulations produced by human articulation instantly produce their corresponding variations of frictional resistance, and the diaphragm reproduces to the ear of the receiver, in a loud and magnified tone, words or other sounds uttered or produced upon the diaphragm of the telephone at the other end of the wire. Mr. Johnson gave us this information in reply to questions which were addressed to him, and made it evident to us that he possesses as thorough a practical knowledge of all points connected with the instrument as a good seaman possesses of the compass.

"Now," said Mr. Johnson, closing the little door of the instrument, "I will ring the bell in the central station." He touched a little knob, and instantly came a ring. "That's the answer," he explained; and then, placing his mouth at the telephone, he called "Hallo, hallo!" (a contraction, we presume, of "Hail, ho, ho!) A reply, "Yes, sir. What can we do for you?" "Well, put me on to the store room."

There followed a little business conversation, and then Mr. Johnson placed us in conversation with a station at Norwood, which is fifteen miles off "by wire." "Do you have to pick out your words, or simply ordinary conversational tones?" we asked, before commencing to hold a conversation with an unknown gentleman at fifteen miles by wire, and, perhaps, eight as the "crow flies." "Oh!" said Mr.

14 24

Johnson, "if a person 'mumbles' in his ordinary conversation and will speak in the telephone, his mode of speaking will be reproduced, only magnified in its peculiarities." (*Par parenthese.* Would some grace the giftie give some speakers the power to hear themselves as others—especially the Press—hear them!) We held a short conversation with Norwood; but, as our purpose was to listen and not to talk, we only spoke with the purpose of listening to the speaker at the other end. That he heard us was soon seen in the immediate compliance with our requests. The gentleman whispered, and words without tones—that is to say, with only breath forms—came back. Then we had a raised tone, and every word could be heard distinctly at several yards' distance from the instrument. The gentleman of Norwood gave us a song, and though we must confess, in candour, that the metallic rendering of the "human voice divine" was far from musical, yet the song could be distinguished in words, modulations of the voice, and in the various keys. The various sounds in a solo on the whistle by the human lips were also clearly and distinctly conveyed. Mr. Johnson informed us that it was quite possible to separate the metallic sound from the other, and to convey the harmony without what we may term the metallism by telephone—that, indeed, this had been done in America over long distances, an effect produced simply by the use of a wooden sounding-board in the receiver. The human voice could be reproduced perfectly through the telephone, if necessary; but he laughingly declined to pledge himself that Mr. Sims Reeves, for instance, could, by the telephone, be able to sing to a Crystal Palace audience by electricity while chanting at Albert Hall—that is to say, in such a manner as to be a commercial success. In general, the voice heard would be a new sound in the cosmos—the "telephonic voice," a distinct and clear voice, but still a voice with a certain amount of metallic or hollow sound.

We had proof of the telephone's efficacy in the transmission of sound—this being the middle of the day in the busy city of London, and yet, east, west, north, and south, with the rattle of trains, the rumble of vehicular traffic, and the multitude of noises, which, in the aggregate, may be heard in a hum miles distant from the city, the voice by telephone came back distinct and clear; and Mr. Johnson then gave us a few passages from the history of the instrument, first, as to the steps in the history of the conveyance of sound discovery by Mr. Edison; then the history of the receptive powers of a receiver, and then the history of the "receiver," the invention of which caps the whole, and makes the telephone a perfect instrument, blessing with the knowledge of an accomplished task "him who gives as well as him" who receives a message.

We then went into the "central exchange," where there are ranged lines of little brasses, like the coverings to the key-holes of large safes. Each of the little brasses represented, so Mr. Johnson informed us, a subscriber. There was a large quantity of material, looking like tangled fishing lines, behind the little brasses, and these were the telegraphic connections. At the tables were the "telephone voices," ready to answer any subscriber and place him in communication with any other subscriber. We had not been two minutes in the "exchange," before down fell one of the little brasses, displaying a number. A plug was placed in a hole below the brass, when the exchange voice asked, "What can I do with you, sir?" The voice of one of our metropolitan administrators, speaking as the head of a firm half-a-mile to the west, asked, "Have you made communication with Messrs. Blank and Co.'s yet?" The reply given, "Not yet ready, sir." "Thanks," was the response, "Good-day" being the closing words on our side, and that interview was closed. "That gentleman knows that we are placing up a telephone for others, and he wanted to know if all was ready," was the explanation given to us. While Mr. Johnson was speaking, down fell another brass. For an instant the "wire" of the receiver was communicating with No. 3. "What can I do for you, sir?" "I wish to speak to Mr. Blank, of Blank-court, Lothbury." "Yes, sir; you are connected," a point being inserted to another number. The point or peg so inserted in the little hole connected the two wires as effectually as if they were torn from the wall and twisted together, and the removal of the peg acting again as an untwisting of the wires. All these operations were quickly and quietly done. The operators, who are the medium of communication between the subscribers, have each a circuit, and their work, it can be seen at a moment's reflection, has been regulated by a perfect organisation.

The "Edison" Company has the Central Exchange at 11, Queen Victoria-street, and City branch "exchanges" at 77, Cornhill, 34, Eastcheap, and in Lonsdale Chambers, Chancery-lane, and at Westminster, while the same company is about to open exchanges on Holborn Viaduct, in Pall Mall, Southwark, Aldersgate-street, Regent-street, and Paddington. "Our great difficulty," said Mr. Johnson, "is to obtain permission to erect poles for the wires. We have obtained permission from some of the authorities holding rule over important public buildings, and we regard that as a great gain. We do not think that public opinion is wholly alive to the importance of telephonic communication; but the fact (stated by one of the company present respecting the introduction of gas) that the gas companies sent round people to ask if the gas should be laid on at the 'same time as next door had theirs,' a neighbourly jealousy which carried the day, shows that the public mind here has to be educated to a want. Our numbers are, however, daily growing. We have now about 160 persons daily calling at the Exchange wishing to be placed in communication with subscribers—that is to say, that subscribers have their time saved by their correspondents communicating with them directly by the telephone. Besides the number who daily call for business purposes, we have many who call to see the working. We did not practically commence until four months ago, so that we have not been yet long before the public in work, and we have here a printed list of the chief firms connected, being nearly 250 subscribers connected under the 'Edison,' so that we are progressing pretty rapidly."

We remarked that our practical experience in the working of the telephone system in America led us to think that the existence of two systems here would be injurious to both, or, rather, would lessen the ability of both to "go ahead" to the extent that an amalgamated company would, and it was acknowledged that two companies would not be so advantageous as one; but it was naively added that two were better than none. We sauntered out of the business-room, and as we went our conductor held that the "Edison" had great advantages over the "Bell," in the fact that the former gives no uncertain answer—that the magnified sound is an unquestionable advantage—that the system in transmitting the message will "largely neutralise the opposing inductive currents due to underground or adjacent telegraph wires," and certainly the fact of the loud-tone speaking of the instrument was amply demonstrated. We had a glance of some other Edison wonders, and we left the Victoria-street Exchange with the idea strongly predominant that Mr. Edison's friends have their faith in his inventive powers well founded, and that those who judge otherwise are of the class for whose backs Solomon said rods were made.

Now we come to the special consideration of the "Bell" telephone. We will at once say that we shall not touch by even so much as a word upon any matters which may be in dispute between the two companies working under the names of "Edison" and "Bell;" our purpose is only to lay before our readers the merits and advantages to be derived from the use of either, while in the interests of the public generally we cannot but express the hope that some means will be found to have telephonic communication cemented in London, at all events, by telephonic union. On going to the head exchange of the "Bell," even if we had not the exact house before us in Coleman-street, we should have been able to pick out the "Exchange" from the forest of wires overhead. Some ancient artist, a few centuries ago, seems to have hit upon the particular spot where the chief "Exchange" stands as the very place whence the dead world was to be awakened to the sound of the trumpet—a solo representation in wood, of Scriptural interpretation, being placed over the disused burial-ground next door, and might be taken, by those who love auguries, as having foretold that the world, at present almost dead to the advantages of the telephone, would be from here awakened. Making our way to the first floor, we are introduced to Mr. H. F. Lewis, the acting general manager, who, in answer to our questions, states that the real working only commenced late last year, but that in London alone there were nearly 400 subscribers, and that the company was also at work in all the great towns. Mr. Lewis handed to us a double list of the subscribers, one being a list in which the subscribers are arranged in alphabetical order, for readiness of reference, with their telephonic number, and the other being as they stand in the order of the instruments. The company have exchanges in Coleman-street, Leadenhall-house, Leadenhall-street, Palace Chambers, St. Stephen's, Westminster. A large map of London stood on the wall, about four feet square, and the immense amount of business which may be done can be judged from the fact that, leaving out the line to Westminster, the communications made could be covered on the map by a man's hand. Mr. Lewis presented us with this statement:—

"Each subscriber has a wire from his residence or office, with the necessary instruments attached, to the telephone company's stations. A signal from the subscriber is answered by the operator at the central station, who instantly makes a connection with the wire of any other subscriber with whom communication is desired, and conversation can then be carried on with ease and privacy, without the possibility of any third person hearing what is passing. A signal to the operator intimates when the conversation is finished. There are no complicated or delicate parts in the instrument requiring any previous knowledge or care; and the words are not only heard clearly, but the voices of speakers can readily be recognised. For a fixed annual rental the company erect and maintain the wires and all requisite apparatus. The only charge for subscribers within a radius of a mile from the company's station is a subscription of £20 per annum, payable in advance."

The rules under which a telephone is held are as follows:—

"The undersigned lessee of telephones agrees to take good care of the same, and all fixtures connected therewith, and will not permit any one not a subscriber to use the instruments, and will not transmit messages for hire, or use the instruments upon any other line or at any other place except as herein specified, and at the expiration of the time for which this agreement is made will surrender the same to the telephone company, or its authorised agents, in as good condition as when received (ordinary wear alone excepted); and in default of payment as herein-below agreed, or in case of the violation of any of these conditions, the lease shall, at said company's option, terminate; and said company, or its authorised agents, shall have the right, and the lessee hereby gives them permission, to enter upon the premises wherein said telephones may be, and take possession of and remove said telephones and fixtures, and the lessee shall have no claim for the repayment of any moneys which may have been paid for rent or otherwise under this lease. In case either of said instruments is lost or destroyed, it is agreed that the lessee shall pay the lessor for each instrument so lost or destroyed, but the property in such instrument shall still remain in the lessor, and such payment of liquidated damages shall give no right to use such instrument. The company is to keep said telephones in good working order, and repair the same at its own expense, except when injured by the carelessness or neglect of the lessee or servants thereof, and is to have free access, at all reasonable times, to the instruments and premises where they are used, for the purpose of inspecting or repairing the same."

After receiving this information we were introduced to the engineer, who led us to the "switch room," as the apartment is termed where the connections are made. Here the subscribers' connections are shown on bars of double alphabets, and the connectors sit at four tables and "switch" on and switch off the subscribers on receiving the message. The transmitting telephone is on pretty much the same principles as the Edison—the difference being so nice that only an expert could appreciate it. The great difference between the two is in the "receiver"—that part which communicates the message to the ear. This, in place of standing out from the telephone, as in the "Edison," is attached by wire to it, and is held to the ear, when the message is heard by the receiver alone. The transmitter does not require, as in the "Edison," to have the mouth of the sender close to the mouth of the telephone; but the person may speak into it at a little distance, while the receiver of the "Bell" gives whatever advantage is derived from the message communicated being a private one, and communicated only to one ear. In this room we saw that the communication between the subscribers were received, and made as described in the "Edison" working, but in place of the little brass shutter falling to denote a message from a subscriber a disc falls, and the communication is made with a plug, which combines the wires of the communicating telephones. After admiring the order and organisation of the office, and expressing our hope that the great list of eminent merchants, firms, and offices would be increased to the full extent of the company's powers, we departed with the full resolve to spare ourselves from the plague of printers' devils in future by entering into telephonic communication with that part of the world which has been wise enough to find that to be without it is equivalent to being without the postage, telegraphic, and railway systems combined.

25

14 226

nature June 17 1880.

Mr. W. P. Johnson gives an account in the *Philosophical Magazine* of a new use of the telephone. It is sometimes necessary to grapple and lift a faulty cable, and if it lies in the water along with other cables of similar exterior make it has hitherto been impossible to decide, without cutting it apart, on the identity of the grappled portion. To avoid the obvious evil of having to cut and splice the cable unnecessarily, it is now suggested to employ the telephone on an auxiliary parallel wire in which the induction may be sufficiently strong to enable the electricians in charge to read the signals which may be sent into the cable, and so identify it.

ELECTRICITY.

Science July 17 1880

An interesting experiment which seems to have a bearing on the action of Edison's friction telephone, has been recently described by Herr Koch. When a plate of platinum or palladium is polarized by means of an electric current, the friction of these metals against a plate of moistened glass increases immediately. To measure the friction, Herr Koch uses the metal in the form of a hemispherical button, resting on the bottom of a glass cup, filled with pure or acidulated water. The button serves as pivot to a magnetic needle, which oscillates under the action of the earth; the decrease of the oscillations measures the friction of the pivot. Polarization is produced by the current of the Daniell element, one pole of which communicates with the metallic button, while the other terminates with a platinum wire entering the water of the cup. The polarization by hydrogen produces no effect, but polarization with the pole oxygenated is found very efficacious. The friction was increased, through this polarization, in the ratio of 2 to 3, and sometimes in that of 2 to 4. This increase of friction appears immediately the circuit is closed, and disappears immediately when the current is reversed; but it disappears slowly, like the polarization itself, when the circuit is merely opened. It increases with the electromotive force of the polarization by oxygen. Palladium behaves like platinum. Gold (18 carat) gave no effect.

REPORTING BY TELEPHONE.

Cincinnati Daily

How Late Speeches in the House of Commons are Dealt With by Modern Scientific Inventions.

Gazette

From the London Times, May 7. June 9 1880

A new method of reporting the late debates of the House of Commons—those, namely, which are continued after midnight—has within the last few days been brought into operation in the office of this journal, and some account of the method employed will probably be of interest to the public. There has for sometime been a tendency among the most prominent public men to deliver their Parliamentary speeches at very late hours, and this, together with the dispatch of the first morning trains from the London termini an hour earlier than formerly, has placed great difficulties in the way of Parliamentary reporting. After about 1 o'clock in the morning, to produce in time for the early edition a full report of a speech, however important it might be, became a matter of extreme difficulty, and after 2 the record of proceedings became necessarily a mere abstract. But these difficulties seem now to be in a fair way to yield—sufficiently at least for all practical purposes—to the increased powers of work which have been afforded by the judicious application of modern scientific inventions. The first step in this direction must undoubtedly be ascribed to the increased rapidity of setting up type, which has been due to the employment of a machine as a substitute for the manual labor of the compositor. The most skillful workman, setting up type by hand, would not exceed a general average of about forty lines per hour, or a maximum rate of fifty lines per hour, during short periods of great pressure; but the machine, in which the types are brought down and placed in position by striking upon keys something like those of a piano or organ, enables a fair workman to attain an average speed of 100 lines an hour, even when composing from manuscript, which he has to read for himself; and this speed can be doubled, or nearly so, when the operator is assisted by a reader and thus composes from dictation. The original form of the machine in use at this office was introduced here soon after the Franco-German war, and has ever since been undergoing such modifications in detail as experience has from time to time suggested, until it has now reached a state of very great efficiency. It has for some time been the custom to transmit the foreign intelligence from Paris, Vienna, and Berlin to this office by means of Hughes printing telegraph, and to dictate the contents of the telegraphic slip to a compositor at the machine. By this combination remarkable facilities in dealing with late manuscript have been obtained, and it has been possible to carry on the work of type setting almost to the time of going to press; but the copy received from the House was necessarily somewhat delayed while the reporter transcribed his notes and in transmission. The compositor was compelled to lag behind the actual progress of the debate, and precious time thus lost at each step of the process mounted up in the end to a considerable total.

At this stage in the history of the matter the telephone was brought into actual operation as a means of vocal communication between distant points, and the conductors of this journal formed a new connection between the House of Commons and the office, and placed one of Edison's loud speaking telephones at either end. The immediate result of this arrangement has been to bring the compositor at the machine into direct communication with the Parliamentary reporter at the House, and to enable the debates to be reported and printed from half to three-quarters of an hour later than had previously been possible. The notes made by the reporter can be read directly into the telephone receiver in a room adjoining the gallery, either by the reporter himself when relieved or by another person employed for the purpose, and the compositor, at his machine in the office, sits with his ears in juxtaposition with the other terminal of the instrument. The plan which has been found the most efficacious for the purpose of shutting out distracting sounds of other kinds is to place the disk of the telephone above and behind the compositor, and then to arrange two tubes, each with two trumpet shaped extremities, in such a manner that these extremities are applied at one end to the two sides of the telephone disk and at the other end to the two ears of the compositor. The compositor is also furnished with a speaking instrument, with a key for ringing a bell, and within hail which is rung from the House; a simple code of bell signals, consisting of one, two, or three strokes, sufficing for the ordinary requirements of each message. The compositor announces by the bell that he is ready, receives a sentence, strikes the bell to indicate that he understands it, sets up the type with his machine, strikes the bell again for the reader to continue his dictation, and so on until the work is carried as far as time will allow. If there is any doubt or difficulty about the word, a bell signal will cause them to be repeated, or explanations can be sought and received by direct vocal communication. In this power, indeed, resides one of the chief advantages of the method, and one which ought to lead to greater accuracy than has ever previously been attainable. The names of people, places, etc., can be spelled out letter by letter if there is any doubt about them.

The Telephone and Deafness.—Some writers on science do not seem to know it has long been well understood that certain forms of deafness are partially remedied by receiving the sounds through the mouth. The ticking of a watch, which cannot be heard when the watch is placed against the ear, is audible when the watch is put into the mouth, and so on. The Milwaukee *Sentinel*, when describing the Elgin Acoustic Telephone, says:—"It is extremely simple and economical in construction." The article states:—"But the most wonderful test is the one which has been tried of getting at such a distance from the instrument that by no possibility can sounds be heard, and then taking the wire between the teeth. A person quite deaf can understand words spoken in a moderate tone, the effect being the same as follows from the use of an audiphone."

Engineering News. May 21. 1881.

THE ELECTROPHONE.

An experiment of great importance has just been made at Calais, France. Between that place and Dover, England, conversation has been kept up by means of a new kind of telephone called the electrophone, attached to the telegraph lines between the two places. The listener at Calais was able distinctly to distinguish not only the words of the speaker at the other end, but also to recognize the speaker by his tone of voice. During the time that the conversation was going on the wires were being used for the transmission of messages by telegraph, and that transmission was made without any interruption whatever. The inventor of the electrophone is of opinion that it can be used in connection with an Atlantic cable, and the success of his experiments so far seems to justify his belief.

Teléfonos.—Por cuanto se ha presentado don Tomas Alva Edison solicitando privilejio esclusivo para construir y usar en el pais unos aparatos telefónicos de su invencion; visto el informe de los peritos don G. R. Gapp y don C. L. Rowsell, y habiéndose cumplido con todos los requisitos que prescriben las leyes de 9 de setiembre de 1840 y de 1.° de setiembre de 1874;

Por tanto, vengo en espedir a favor de don Tomas Alva Edison patente de privilejio esclusivo por el término de ocho años para construir y usar en el pais dichos aparatos, tales como se encuentran descritos en el diseño y pliego de esplicaciones depositados en el museo nacional.

Los ocho años comenzarán a contarse despues de trascurrido uno, que se asigna al interesado para que ponga en ejercicio su industria.

Este privilejio no comprende el uso del aparato destinado a hacer sonar campanas, descubrir número y tablas cambiantes, por ser ya conocido en Chile.

Dada en Santiago de Chile, a 30 dias del mes de abril de 1880.—Pinto.—Domingo Santa Maria.

Ensayo del teléfono.—Anoche las personas que habia en la oficina telegráfica trasandina de Santiago se han comunicado y conversado perfectamente por el teléfono con otras personas que estaban en la oficina central recien establecida en Valparaiso.

El señor Husbands ajente de la compañía del teléfono de Edison, hizo llamar a su esposa que estaba cerca de la oficina en Valparaiso. Habiendo llegado la señora, a invitacion del señor Husbands se puso a cantar el *Miserere* del *Trovador*, al fin de cuya pieza el esposo hizo dúo con su señora. Terminado el canto de la artista, que fué escuchado con mucho interes por todos los concurrentes de Santiago, el auditorio manifestó su satisfaccion con una salva de aplausos, a los que contestó la artista desde Valparaiso dando las gracias.

Todos los asistentes de Santiago y Valparaiso hicieron recíprocas preguntas, dándose las respectivas contestaciones. Uno de ellos, entre otros, llamó desde Santiago a la oficina de Valparaiso a un amigo a quien le habia remitido una encomienda. Acudió el amigo al llamado.

—¿Has recibido, preguntóle el amigo de aquí, la encomienda que te mandé el domingo?

—Sí, y en buena condicion, contestó el otro inmediatamente.

—Muchas gracias.

Y no hubieron mas a estilo de comerciantes.

Lo que se hablaba desde Valparaiso y hasta las risas de los concurrentes de la oficina de ese puerto, se oian claramente en todos los ámbitos de la oficina de Santiago.

Este ensayo del teléfono ha sido como una fiesta en celebracion del decreto espedido ayer por el gobierno en que se concede privilejio esclusivo a la compañía empresaria del teléfono.

Hai varias casas comerciales de Santiago que están ya dispuestas a valerse del teléfono para conversar sobre negocios al traves de 40 leguas, a ejemplo de algunas casas de Valparaiso que ya tienen establecidas ramificaciones telegráficas con la oficina central de ese puerto.

Segun el empresario que una vez que esté bien establecida y correcta la línea, se oirá en Valparaiso el ruido de los carruajes que pasan por la calle cerca de la oficina de Santiago.

A USEFUL MICROPHONE.

[18928.]—THE following details of a microphone will, I am sure, interest our various readers who have made this wonderful instrument a study. I do not claim for the instrument originality, but adaptation of the principle of the first microphone of Professor Hughes.

After many experiments, and patient trials of most existing forms of microphones, the one I describe will be found to have many good qualities. Commencing with the diaphragm, this is constructed of white or yellow pine 1-12th of an inch thick, and 5in. square; on the edges are glued two strips of wood about 3-16 thick, shaped like a bridge, about ½in. at the middle, and tapering gradually at the ends; these are glued across the grain, and prevent the soundboard twisting, Fig. 1.

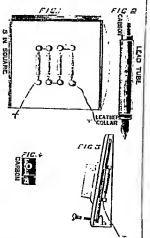
The carbon pencils (Fig. 2) are made from electric-light pencils, No. 2, obtained from Mr. E. Paterson, 76, Little Britain, and the pencil-holders from No. 5 pencil. The pencils are 2in. long, nicely filed to a point, and fitted into a small leaden tube (Fig. 2). The tube used for pneumatic bells answers well. Round the carbon is glued a collar of leather, which secures the lead in place, and acts as a damper in preventing the sound given by the carbon itself. This sound is heard if a small piece of carbon is struck, and is the cause of the metallic sound so often heard in microphones. The length of the lead tube should be 1in. and 3-16.

The pencil-holders are cut about 7-16 long, a hole drilled half-way through, and a groove cut round (Fig. 4). Four carbons are glued to the soundboard, and, when dry, the pencils put in place loosely by placing the remaining four carbons. A piece of thin copper wire, cleaned well, about No. 30, is placed in the front in the carbon holders, and twisted up, and a touch with soldering-iron afterwards makes all secure. On the opposite side of diaphragm is lightly glued a rubber ring, about 2½in. in diameter, which rests when in box against the front, and the pressure regulated by a screw (see Fig. 3), filed to a square, and moved by a key. This rubber ring acts as a damper, and prevents noise and rattling.

The soundboard is fastened to the inside of the box by a leather hinge glued along the upper edge, and on a slip of wood, the thickness of rubber ring, a small spring presses at the lower edge of board, which keeps it close to the screw (see Fig. 3).

The soundhole in mouthpiece is 1in. in diameter, and the box made of well-seasoned mahogany, ¾ or ⅝in. thick, solidity being essential; the internal diameter of box about five inches and a half, leaving a space about a quarter of an inch all round board, except at upper edge, where the leather hinge is glued on.

When the adjusting screw allows the diaphragm to press lightly on front of box, the instrument is in order for speaking, and eight to ten inches



distance gives first-rate results. The voice should be just as in ordinary conversation: music, such as violin, is beautifully heard through a telephone receiver.

The above is a description of a pair of instruments I constructed twelve months ago, and their behaviour is so good that, for the benefit of our amateur subscribers, I give you a description of this modified form of microphone.

Two or three Leclanché cells are sufficient for ordinary purposes. The microphone can be used well without induction coil, and can be fixed to any of the existing arrangements with switch and bell. The angle of microphone box, I should state, is from ten to twelve degrees. The ones I have constructed rest at 10°, and answer admirably.

Cette Compagnie des Téléphones, de plus des compagnies similaires américaines, a adopté plusieurs instruments nouveaux, entre autres le téléphone Gower, téléphone sans pile électrique, l'appareil de cet ordre le plus simple et qui présente les résultats les meilleurs.

Nous avons donné une description complète (*Science pour Tous*, année 1878) de ce téléphone, l'un des appareils dont la Compagnie des téléphones a acquis la propriété d'utiliser. Rappelons que cet appareil

Avec cet appareil, nul besoin de pile, nulle dépense supplémentaire, nulle chance de dérangement parce que dans un moment d'oubli on aura omis de rompre, la communication terminée, et que la pile soit épuisée.

L'appareil, accroché au mur comme un cartel ou rapporté assez bien par sa forme celle d'un baromètre, est muni d'un porte-voix monté à l'extrémité d'un tube flexible. C'est en soufflant dans ce tube, que l'on actionne au poste correspondant une lame vibrante produisant un son intense et de la même manière que ce poste indique qu'il est prêt à écouter et à répondre.

Rien de plus curieux que l'installation du bureau central.

Dans une salle, le long des murs, sont aménagés un certain nombre de compartiments distincts ayant chacun son tabouret, sa tablette, son téléphone, un cornet acoustique pour renforcer en cas de besoin les sons téléphoniques perçus par l'oreille, et fixé au mur, un tableau commutateur, portant des numéros servant à établir les communications entre les correspondants. Le bureau central se trouve relié par des fils conducteurs ou fils télégraphiques, courant dans les galeries d'égouts avec le domicile de chaque abonné. Des employés, mis à la disposition d'un certain nombre d'a...

branches, et il parait ... que les arbres ainsi pratiques ... plus chargés de fruits ... découverte.

Cette précaution ... qu'un nous ne saurions ... pour le croire, et ... teuse que l'on ... trora aux personnes ... si les résultats sont tant et à ...

REPORTING BY TELEPHONE.

We quote the following from the *Times*: "A new method of reporting the late debates of the House of Commons—those, namely, which are continued after midnight—has within the last few days been brought into operation in the office of this journal; and some account of the method employed will probably be of interest to the public. There has for some time been a tendency among the most prominent public men to deliver their Parliamentary speeches at very late hours, and this, together with the despatch of the first morning trains from the London terminal an hour earlier than formerly, has placed great difficulties in the way of Parliamentary reporting. After about one o'clock in the morning to produce in time for the early edition a full report of a speech, however important it might be, became a matter of extreme difficulty, and after two the record of proceedings became necessarily a mere abstract. The inevitable curtailment of the reports has been felt as a grievance by many members of the House, and has been one cause of the efforts recently made, by appointing Select Committees and otherwise, to get a better provision for the publication of the debates. But these difficulties seem now to be in a fair way to yield—sufficiently at least for all practical purposes—to the increased powers of work which have been afforded by the judicious application of modern scientific inventions.

"The first step in this direction must undoubtedly be ascribed to the increased rapidity of setting up type, which has been due to the employment of a machine as a substitute for the manual labour of the compositor. The most skilful workman, setting up type by hand, would not exceed a general average of about 40 lines per hour, or a maximum rate of 50 lines per hour during short periods of great pressure; but the machine, in which the types are brought down and placed in position by striking upon keys something like those of a piano or organ, enables a fair workman to attain an average speed of 100 lines an hour even when composing from manuscript, which he has to read for himself; and this speed can be doubled, or nearly so, when the operator is assisted by a reader, and thus composes from dictation. The original form of the machine in use at this office was introduced here soon after the Franco-German war, and has ever since been undergoing such modifications in detail as experience has from time to time suggested, until it has now reached a state of very great efficiency. It has for some time been the custom to transmit the foreign intelligence from Paris, Vienna, and Berlin to this office by means of Hughes's printing telegraph, and to dictate the contents of the telegraphic slip to a compositor at the machine. By this combination remarkable facilities in dealing with late manuscript have been obtained, and it has been possible to carry on the work of type-setting almost to the time of going to press; but the delayed while the reporter transcribed his notes and in transmission. The compositor was compelled to lag behind the actual progress of the debate, and precious time thus lost at each step of the process mounted up in the end to a considerable total.

"At this stage in the history of the matter the telephone was brought into actual operation as a means of verbal communication between distant points; and the conductors of this journal, having obtained permission from the Metropolitan Board of Works to lay down the necessary wires in the subway of the Embankment, formed a new connexion between the House of Commons and the office and placed one of Edison's loud-speaking telephones at either end. The immediate result of this arrangement has been to bring the compositor at the machine into direct communication with the Parliamentary reporter at the House, and to enable the debates to be reported and printed from half to three-quarters of an hour later than had previously been possible. The notes made by the reporter can be read directly into the telephone receiver in a room adjoining the gallery, either by the reporter himself when relieved or by another person employed for the purpose; and the compositor, at his machine in the office, sits with his ears in juxtaposition with the other terminal of the instrument. The plan which has been found the most efficacious for the purpose of shutting out distracting sounds of other kinds is to place the disc of the telephone above and behind the compositor, and then to arrange two tubes, each with two trumpet-shaped extremities, in such a manner that these telephone disc and at the other end to the two sides of the extremities are applied at one end to the two ears of the compositor. The compositor is also furnished with a speaking instrument, with a key for ringing a bell, and with a bell which is rung from the House; a simple code of bell signals, consisting of one, two, or three strokes, sufficing for the ordinary requirements of each message. The compositor announces by the bell that he is ready, receives a sentence, strikes the bell to indicate that he understands it,

The Edison Telephone.—Edison telephones have been installed at the Pic du Midi Observatory, and afford easy communication with Bagnères, a distance of 15 miles. The first experiment failed, owing to the cloudy and stormy intervening stratum of air, but with improved instruments every sound pronounced in the ordinary conversational pitch is distinctly audible.

SLIP

The Electro-Motor Telegraph.—Edison has sold his electro-motor telegraph to the Western Union for £20,000.

Druggists Circular

New Use for the Telephone.

It is reported that the London *Times* has placed its composition room in telephonic communication with the House of Commons, and is thus enabled to put in type with greater dispatch the debates and proceedings of that body, and frequently to publish accounts of such proceedings half an hour or three-quarters of an hour later than had hitherto been possible.

The reporter, stationed in a room adjoining the reporters in the house gallery, reads from his notes directly into the instrument, sentence by sentence, and the compositor, with his type-setting machine at the *Times* office, sets up the matter as it is read, signalling the reporter when he has set up one sentence and is ready for the next. A simple code of prearranged bell signals suffices for intelligent communication between sender and receiver. The plan is stated by the *Times* to work very well.

The Telephone.—A motion was made on Thursday morning, July 29, before Vice-Chancellor Malins, to restrain the United Telephone Company from issuing advertisements stating that they were taking proceedings against Mr. Louis J. Crossley, of Halifax, for infringement of their patent for carbon transmitters, pending legal proceedings which Mr. Crossley invited the company to take against him for infringement of the patent. The company are assignees of the Edison patent, and the day after the registration of assignment commenced proceedings against various parties. Mr. Crossley contended that his carbon transmitter, the "compound microphone," was no infringement of the Edison patent assigned to the company. After a short discussion the defendant company undertook not to issue the advertisements complained of, without prejudice to any question of the propriety of the proceedings which had been taken. Mr. Aston, Q.C., Mr. Philbrick, Q.C., and Mr. Macrory, instructed by Messrs. Philbrick and Corpe, 18, Austin Friars, appeared for the plaintiff; and Mr. Glasse, Q.C., and Mr. Cozens Hardy, instructed by Messrs. Waterhouse and Winterbottom, of Lincoln's-inn, appeared for the defendants.

Electrician June 19 1880

NEW TELEPHONES.

The recent amalgamation of the two English telephone companies (the Bell and Edison) is a matter of congratulation. By uniting they will change expensive and annoying warfare into mutual advantage, and occupy the field against all comers. The Edison transmitter, which is hitherto the best of all, will then be used in connection with the Bell receiver, which is likewise peerless of its kind, and the combination of these two instruments will be a benefit to the public.

The progress of telephone research has to some extent fallen off lately, but during last year there were one or two serviceable telephones brought out. Mr. Geo. M. Hopkins recently described an interesting transmitter of his invention in the *Scientific American*. The transmitter is fixed to a bracket, and stands vertically with its sound-collecting mouthpiece pointed in the direction whence the sound proceeds. The receiver, which is an ordinary Bell instrument, stands when not in use over a curved pendent resonator, the smaller end of which projects through the shelf of the bracket, and just enters the hole in the centre of the receiver mouthpiece.

Between the transmitter and receiver there is a small induction coil whose primary wire is connected with the local battery and transmitter. One terminal of the secondary wire of the coil is connected with the receiving instrument and line, the other terminal is grounded. The instrument is an ingenious form of microphone transmitter, and consists, as usual, of a diaphragm and mouthpiece to receive the speaker's voice, a carbon button attached to the under side of this diaphragm, and, pressing up against this button, is a light rod of fine carbon floated in a bottle of mercury. The carbon button is of ordinary battery carbon, the rod of electric light carbon. The bottle is a phial with a rounded bottom like an antique tear-jar. The circuit through this microphonic contact is made by means of a platinum electrode fused into the bottom of the phial so as to reach the mercury, and a wire making contact by means of a light spring with a leaf of copper foil lying under the diaphragm, and fixed between the latter and the carbon button. The current, therefore, passes by one wire, the foil, and carbon button to the carbon rod and mercury, thence by the platinum wire to the line.

The carbon rod is ¼in. in diameter and furnished with a round point, which is pressed by the buoyancy of the mercury against the under surface of the button, which is filed as plane as it can be. Hence the vibrations of the diaphragm, besides pressing the microphone contact, also dip the rod into the mercury, which forms a very equable fluid spring. The height of the telephone is about six inches.

The diaphragm, which is of mica, is rather stiff and firmly clamped in its chamber, the frame being of wood, well soaked in paraffin, or, better, vulcanite, so as not to be liable to warp.

The induction coil used with the instrument is of the ordinary form, two inches long, one inch in diameter, with a ⅜in. core of No. 18 soft iron wire. The primary coil consists of ... covered copper wire, and the secondary of No. 36 ... quantity to fill the spool. One cell of Leclanché battery will work the transmitter, but two will ... volume of sound.

As to the efficiency of the instrument, it will bea[r] ... with other transmitters, and in one or two point[s] ... have a slight advantage. It will transmit speech ch[arly if] the speaker be within ten miles or as many feet from th[e] ... Although a call bell may be used in connection with ... none will be required, as by saying 0-0-0-0 loudly int[o the mouth]piece a trumpet-like note is heard at the other end ... the receiver there, which, though not very loud, is ... attract notice in a tolerably quiet room. It would ... imagine, for Mr. Hopkins to add an efficient call to ... ment, and he would thereby greatly improve its effi[ciency, for a] weak call is a decided disadvantage.

Another promising transmitter is the micro-tele[phone trans]mitter by Mr. Hunnings, which was patented in ... since then been brought by degrees to a very efficient ... earlier form consisted of a diaphragm of ferrot[ype,] platinum or silver, and a disc of brass placed nea[r,] the intervening space being filled with carbon p[owder] 1-16 inch deep.

The circuit was made through the diaphragm and ... brass disc, and the whole was secured in a small co[m]... wooden case. The carbon powder was preferably ... engine coke, and it was an essential feature that it sh[ould be in a] loose free state. The only difference, indeed, be[tween this] transmitter and Edison's is the looseness of the ca[rbon which] made it an agglomeration of microphone contacts.

The present improved form is mainly due to Mr. C... of York. It was recently exhibited at a meeting of th[e] ... Institution of Engineers, Middlesborough, with very ...

Its outward appearance is similar to that of the or[dinary] ... telephone, which is now so familiar to nearly everyo[ne, but the] resemblance stops there. The usual telephone mo[uthpiece is] covered on the under side of the opening by a piec[e of] plated brass wire gauze, which forms a protection t[o a] sheet of platinum foil, which now acts the part of a ... diaphragm, and is in immediate contact with a very th[in layer of] granulated coke, which fills a small posterior cavity ... with a brass plate at the bottom. The platinum f[oil is con]nected to one terminal through a brass ring, and the ... is connected to the other terminal. The terminal ... passed through a hole down the centre of the handle, ... being screwed on to the central part.

In connecting it up for use a receiving telephone (w... be Bell's or other similar instrument) is, of course, r[equired at] each end of the line in addition to the micro-teleph[one trans]mitter, and also a battery of Leclanché or other cells. ... of this transmitter is, by the aid of the battery cur[rent, to] increase the sound given out by the receiving teleph[one, to] make these instruments a practical success, and also to ... by its power the effects of induction from neighbouri[ng wires,] this latter having hitherto prevented the use of tele[phones on] wires in the neighbourhood of others along which stro[ng] currents may be passing. The success of Hunning[s'] telephone in this respect is undoubted, and its clear ar[ticulation] and power are very striking. The loose granulated coke [between] the two metallic plates is the secret of this success. T[he sound] waves cause more or less of the under surface of the di[aphragm] to come into contact with the grains of coke, at t[he same] time causing these particles to press more clos[ely on] each other, thus decreasing the amount of th[e resist]ance they offer to the passage of the voltaic ... through them by bringing more points into contact w[ith each] other, this action taking place in a greater or less d[egree in] accord with the amplitude of the vibrations of the plati[num foil] acting under the influence of the sonorous waves. The conti[rol] this movement of foil and coke grains exercises over the ... current renders the use of an induction coil, which is fou[nd] so great a necessity with other forms of telephone transm[itters —] Edison's, Crossley's, and Blake's, to wit—quite unne[cessary;] and by the use of a special form of receiver, which is ... gaging the attention of Messrs. Hunnings and Cox-Wal[ker, the] effects of induction are hoped to be entirely elimina[ted. The] experiments hitherto made by them in this direction giv[e pro]mise of ultimate success.

An automatic switch board, with call bell and ring[ing key,] completes the outfit for each end of a line for te[lephonic] purposes.

The instruments were successfully tried not long ago ... York and Darlington, a distance of about forty-five mil[es, the] wire used for the purpose of this test trial being one o[f] twenty of the ordinary telegraph wires which stretch fr[om]

REPORTING BY TELEPHONE.

WE quote the following from the *Times*: "A new method of reporting the late debates of the House of Commons—those, namely, which are continued after midnight—has within the last few days been brought into operation in the office of this journal; and some account of the method employed will probably be of interest to the public. There has for some time been a tendency among the most prominent public men to deliver their Parliamentary speeches at very late hours, and this, together with the despatch of the first morning trains from the London termini an hour earlier than formerly, has placed great difficulties in the way of Parliamentary reporting. After about one o'clock in the morning to produce in time for the early edition a full report of a speech, however important it might be, became a matter of extreme difficulty, and after two the record of proceedings became necessarily a mere abstract. The inevitable curtailment of the reports has been felt as a grievance by many members of the House, and has been one cause of the efforts recently made, by appointing Select Committees and otherwise, to get a better provision for the publication of the debates. But these difficulties seem now to be in a fair way to yield—sufficiently at least for all practical purposes—to the increased powers of work which have been afforded by the judicious application of modern scientific inventions.

"The first step in this direction must undoubtedly be ascribed to the increased rapidity of setting up type, which has been due to the employment of a machine as a substitute for the manual labour of the compositor. The most skilful workman, setting up type by hand, would not exceed a general average of about 40 lines per hour, or a *maximum* rate of 50 lines per hour during short periods of great pressure; but the machine, in which the types are brought down and placed in position by striking upon keys something like those of a piano or organ, enables a fair workman to attain an average speed of 100 lines an hour even when composing from manuscript, which he has to read for himself; and this speed can be doubled, or nearly so, when the operator is assisted by a reader, and thus composes from dictation. The original form of the machine in use at this office was introduced here soon after the Franco-German war, and has ever since been undergoing such modifications in detail as experience has from time to time suggested, until it has now reached a state of very great efficiency. It has for some time been the custom to transmit the foreign intelligence from Paris, Vienna, and Berlin to this office by means of Hughes's printing telegraph, and to dictate the contents of the telegraphic slip to a compositor at the machine. By this combination remarkable facilities in dealing with late manuscript have been obtained, and it has been possible to carry on the work of type-setting almost to the time of going to press; but the copy received from the House was necessarily somewhat delayed while the reporter transcribed his notes and its transmission. The compositor was compelled to lag behind the actual progress of the debate, and precious time thus lost at each step of the process mounted up in the end to a considerable total.

"At this stage in the history of the matter the telephone was brought into actual operation as a means of verbal communication between distant points; and the conductors of this journal, having obtained permission from the Metropolitan Board of Works to lay down the necessary wires in the subway of the Embankment, formed a new connexion between the House of Commons and the office and placed one of Edison's loud-speaking telephones at either end. The immediate result of this arrangement has been to bring the compositor at the machine into direct communication with the Parliamentary reporter at the House, and to enable the debates to be reported and printed from half to three-quarters of an hour later than had previously been possible. The notes made by the reporter can be read directly into the telephone receiver in a room adjoining the gallery, either by the reporter himself when relieved or by another person employed for the purpose; and the compositor, at his machine in the office, sits with his ears in juxtaposition with the other terminal of the instrument. The plan which has been found the most efficacious for the purpose of shutting out distracting sounds of other kinds is to place the disc of the telephone above and behind the compositor, and then to arrange two tubes, each with two trumpet-shaped extremities, in such a manner that these extremities are applied at one end to the two sides of the telephone disc and at the other end to the two ears of the compositor. The compositor is also furnished with a speaking instrument, with a key for ringing a bell, and with a bell which is rung from the House; a simple code of bell signals, consisting of one, two, or three strokes, sufficing for the ordinary requirements of each message. The compositor announces by the bell that he is ready, receives a sentence, strikes the bell to indicate that he understands it,

THE EDISON TELEPHONE.—Edison telephones have been installed at the [illegible] easy communication with Bagnères, a distance of 15 miles. The first experiment failed, owing to the cloudy and stormy intervening stratum of air, but with improved instruments every sound pronounced in the ordinary conversational pitch is distinctly audible.

SLIP

THE ELECTRO-MOTOR TELEGRAPH.—Edison has sold his electro-motor telegraph to the Western Union for £20,000.

Druggists Circular

New Use for the Telephone.

IT is reported that the London Times has placed its composition room in telephonic communication with the House of Commons, and is thus enabled to put in type with greater dispatch the debates and proceedings of that body, and frequently to publish accounts of such proceedings half an hour or three-quarters of an hour later than had hitherto been possible.

The reporter, stationed in a room adjoining the reporters in the house gallery, reads from his notes directly into the instrument, sentence by sentence, and the compositor, with his type-setting machine at the *Times* office, sets up the matter as it is read, signalling the reporter when he has set up one sentence and is ready for the next. A simple code of prearranged bell signals suffices for intelligent communication between sender and receiver. The plan is stated by the *Times* to work very well.

Electrician Aug 7/80

THE TELEPHONE.—A motion was made on Thursday morning, July 29, before Vice-Chancellor Malins, to restrain the United Telephone Company from issuing advertisements stating that they were taking proceedings against Mr. Louis J. Crossley, of Halifax, for infringement of their patent for carbon transmitters, pending legal proceedings which Mr. Crossley invited the company to take against him for infringement of the patent. The company are assignees of the Edison patent, and the day after the registration of assignment commenced proceedings against various parties. Mr. Crossley contended that his carbon transmitter, the "compound microphone," was no infringement of the Edison patent assigned to the company. After a short discussion the defendant company undertook not to issue the advertisements complained of, without prejudice to any question of the propriety of the proceedings which had been taken. Mr. Aston, Q.C., Mr. Philbrick, Q.C., and Mr. Macrory, instructed by Messrs. Philbrick and Carpe, 18, Austin Friars, appeared for the plaintiff; and Mr. Glasse, Q.C., and Mr. Cozens Hardy, instructed by Messrs. Waterhouse and Winterbottom, of Lincoln's-inn, appeared for the defendants.

to pole along the side of the railway. The effects of induction were at times very powerful, but they did not prevent the easy and successful carrying on of conversation or the transmission of ordinary railway cypher messages between the two stations. The instruments exhibited at the meeting were connected on to the private wire of Messrs. Stevenson, Jaques, and Co., to their Acklam Works, where a set of similar instruments were placed. Conversation was then carried on for a considerable time with the Acklam office.

The microphone transmitter of Mr. L. J. Crossley is too well known to require description here; but that gentleman has recently supplemented it by a new receiver which is an ingenious modification of Bell's. An electro-magnet of a square horseshoe form has both poles presented to the underside of the diaphragm. One pole only is surrounded with a bobbin of insulated wire. The internal cavity is filled up with paraffin wax after the poles are adjusted by means of a screw to the proper distance from the diaphragm. This is to render the tone purer. The current is circulated through the bobbin, and the diaphragm is correspondingly attracted.

Another form is made having two of these electro-magnets side by side, acting on the diaphragm. The loudness of the sounds depends, of course, on the strength of the current; but six Leclanché elements give good results on a line nine miles long, when using the Crossley microphone for a transmitter.

At a recent meeting of the Royal Society a paper was read by Mr. Preece on some thermal effects of electric currents, in which he showed that extremely fine wires acquire and lose heat so rapidly, and are so sensitive to expansion from the heating, that, if inserted in the circuit of a microphone transmitter, they reproduce sonorous vibrations. Thus a mere sounding board or disc, and a fine wire, are all that are needed to reproduce speech with the same faithfulness that Bell obtains by electro-magnetic agency, Edison by electro-chemical agency, and Hughes by his microphonic principle.

A similar telephone has also been invented by M. Ader and Count du Moncel, and it will be remembered by our readers that at a recent meeting of the Society of Telegraph Engineers Professor W. E. Ayrton announced that he had just heard in Paris a remarkably simple telephone receiver, consisting merely of very fine copper wire bent into a curved form. If we remember rightly Count du Moncel had shown Professor Ayrton this receiver, and its principle would seem to be identical with that of Mr. Preece.

M. Ader has done some excellent work in telephony of late. The wire receiver is the natural outcome of his first telephone patented in this country last year. In this instrument a bar of iron was loosely encircled with a coil of wire, through which the vocal current flowed, and the molecular expansion and contractions of the bar gave out sound without a diaphragm. The next advance he has made is to dispense even with the bar, and make the thermal expansions and contractions of the wire itself give out sound under the action of the current.

Another form of telephone receiver was brought before the French Academy very recently by M. Ader. It is based on the principle that if a thin plate of iron or steel is placed before the poles of a magnet, it is much more strongly acted on by the poles when a second plate or armature of iron is placed behind it than when that second plate does not exist. This is easily proved by holding a spring in front of a horse-shoe magnet with its poles close together, so as to be attracted, but not sufficiently so to touch the poles. Then, on bringing up the armature behind, the spring will fly inwards to the poles.

The new telephone consists of a Bell receiver with a horse-shoe magnet and an iron diaphragm. Behind this diaphragm a second disc is fixed, having a hole perforated in its centre so as to permit the vibrating air to reach the inner disc. This telephone, through the exalting action of the rear disc, gives louder results than the ordinary Bell instrument.

HOW TO MEASURE THE SIZE OF WIRES.

By M. ROTHEN, Assistant Director of Swiss Telegraphs.

(Translated from the *Journal Télégraphique*.)

At first sight this question seems so simple that many readers might think that they could answer it at once. Yet it has already been productive of many discussions, propositions, and counter propositions within the last twenty years; and, quite recently, a committee formed of names distinguished in applied science was appointed to investigate it. The reason why the mode of indicating the size of wires is not so simple as it appears is that some wish to determine it by a line and others by a surface, in other words, some would take the *diameter* and others the *weight* as a basis of measurement. On the European continent the first method predominates; whilst in England, in the

Sc. Am. July 24. 1880

Setting Type by Telephone

The London *Times* contains an article describing the system of telephonic reporting adopted by that journal, in order to have the latest and fullest report of the speeches made in the Houses of Parliament. Permission having been obtained from the Metropolitan Board of Works to lay down the necessary wires in the subway of the Embankment, a new connection between the House of Commons and the *Times* office was formed, and one of Edison's loud-speaking telephones placed at either end. The immediate result of this arrangement has been to bring the compositor at the machine into direct communication with the Parliamentary reporter at the House, and to enable the debates to be reported and printed from half to three-quarters of an hour later than had previously been possible. The notes made by the reporter can be read directly into the telephone receiver in a room adjoining the gallery either by the reporter himself when relieved or by another person employed for the purpose; and the compositor, at his machine in the office, sits with his ears in juxtaposition with the other terminal of the instrument. The plan which has been found the most efficacious for the purpose of shutting out distracting sounds of other kinds is to place the disk of the telephone above and behind the compositor, and then to arrange two tubes, each with two trumpet-shaped extremities, in such a manner that these extremities are applied at one end to the two sides of the telephone disk and at the other end to the two ears of the compositor. The compositor is also furnished with a speaking instrument, with a key for ringing a bell, and with a bell which is rung from the House, a simple code of bell signals, consisting of one, two, or three strokes, sufficing for the ordinary requirements of each message. The compositor announces by the bell that he is ready, receives a sentence, strikes the bell to indicate that he understands it, sets up the type with his machine, strikes the bell again for the reader to continue his dictation, and so on until the work is carried as far as time will allow. If there is any doubt or difficulty about the words, a bell signal will cause them to be repeated, or explanations can be sought and received by direct vocal communication. In this power, indeed, resides one of the chief advantages of the method, and one which ought to lead to greater accuracy than has ever previously been attainable. The names of people, places, etc., can be spelled out letter by letter if there is any doubt about them.

Reporting by Telephone.

The method of reporting the debates in the House of Commons by telephone, lately adopted by the London *Times*, is thus described by that journal. A type-setting machine has for some time been used in the office, by which a fair workman can attain an average speed of 10(t) lines an hour, even when composing from manuscript which he has to read for himself; and this speed can be doubled, or nearly so, when the operator is assisted by a reader, and thus composes from dictation. Now the telephone has been brought into use in connection with this machine in the following mode. Having obtained the permission to lay down the necessary wires we formed a new connection between the House of Commons and the office, and placed one of Edison's loud speaking telephones at either end. The immediate result of this arrangement has been to bring the compositor at the machine into direct communication with the parliamentary reporter at the House and to enable the debates to be reported and printed from half to three-quarters of an hour later than had previously been possible. The notes made by the reporter can be read directly into the telephone-receiver in a room adjoining the gallery either by the reporter himself when relieved or by another person employed for the purpose, and the compositor at the machine, in the office, sits with his ears in juxtaposition with the other terminal of the instrument.

The plan which has been found the most efficacious for the purpose of shutting out distracting sounds of other kinds is to place the disc of the telephone above and behind the compositor and then to arrange two tubes, each with two trumpet-shaped extremities in such a manner that these extremities are applied at one end to the two sides of the telephone disc and at the other end to the two ears of the compositor. The compositor is also furnished with a speaking instrument, with a key for ringing a bell and with a bell which is rung from the House—a simple code of bell signals, consisting of one, two, or three strokes, sufficing for the ordinary requirements of each message. The compositor announces by the bell that he is ready, receives a sentence, strikes the bell to indicate that he understands it, sets up the type with his machine, strikes the bell again for the reader to continue his dictation, and so on until the work is carried as far as time will allow. If there is any doubt or difficulty about the words a bell signal will cause them to be repeated, or explanations can be sought and received by direct vocal communication. In this power indeed resides one of the chief advantages of the method, and one which ought to lead to greater accuracy than has ever previously been attainable. The names of people, places, etc., can be spelled out letter by letter if there is any doubt about them.

Tel. Journ.

ON CURRENTS PRODUCED BY FRICTION BETWEEN CONDUCTING SUBSTANCES, AND ON A NEW FORM OF TELEPHONE RECEIVER.*

In a communication to the Royal Society of Edinburgh, of date January 6th, 1879, I showed that "electric currents were produced by the mere friction between conducting substances." The existence of these currents can be easily demonstrated either by a telephone or a Thomson's galvanometer. I have since found that these currents are, for all pairs of metals which I have yet tried in the same direction as the thermo-electric current, got by heating the junction of the same two metals. They are also, approximately at least, stronger in proportion as the metals rubbed are far apart on the thermo-electric scale—the strongest current, as far as I have yet observed, being got by rubbing antimony and bismuth together. These observations clearly point to a thermo-electric origin for the currents; but it is possible that they may be due partly to the currents suggested by Sir William Thomson as the cause of friction, and partly, also, to contact force between films of air or oxide adhering to the surfaces of the metals.

Having ascertained that these friction-currents are of some strength and fairly constant, I proceeded to make several kinds of machine for producing currents on this principle. One of them consists of a cylinder of antimony, which can be rotated rapidly, while a plate of bismuth is pressed hard against it by a stiff spring. When this machine is included in the same circuit with a microphone and a Bell telephone, the current got from it is quite sufficient to serve for the transmission of musical sounds and also loud speaking. The transmitter which I have found most serviceable in my experiments is made by screwing two small cubes of gas-carbon to a violin, and placing between them a long stick of carbon pointed at both ends, the points being made to rest in conical holes in the carbon cubes. The looseness of the contact is regulated by a paper spring. This forms an excellent and handy transmitter for all kinds of musical sounds, and also serves very well for transmitting speech.

Seeing that friction between metals clearly produces a current, it seems natural to inquire if the converse held good, that is, if a current from a battery sent across the junction of two metals affected the friction of the one upon the other. I have tested for this in a variety of ways, and the results obtained leave me in doubt whether to attribute them to variations in the friction or to actual sticking produced by fusion of the points of contact through which the current passes. The most noticeable effect is produced when one of the rubbing bodies is a mere point and the other a smooth surface of metal. This led me to make a modification of the loud-speaking telephone of Mr. Edison, in order to get audible indications of changes of friction produced by the passing of a variable current. It consists of a cylinder of bismuth accurately turned and revolving on centres. The rubbing-point is made of a sewing-needle with its point bent at right angles, and its other end attached to the centre of the mica disc of a phonograph mouthpiece. It is evident that this is only a loose contact, which can be perpetually changed. When this apparatus is included in the circuit with the violin-microphone and three or four Bunsen cells, the violin sounds, as was to be expected, are heard proceeding from the loose-contact, even when the cylinder is not rotated. They are increased, however, in a remarkable degree by rotating the cylinder slowly, so much so that a tune played on the violin can, with proper care, be distinctly heard all over an ordinary room.

With regard to the explanation of this effect, it is evident that electrolysis can in no sense come into play, as is supposed to be the case in Edison's instrument. I am inclined to look for the explanation rather in the direction of the Trevelyan rocker, although the circumstances are considerably different in the two cases. In the rocker we have the heat passing from a mass of hot metal through two points of support to a cold block, whereas, in the other case, the heat is only intense at the points of contact, the rest of the metals being comparatively unaffected. The variations in the current produced by the transmitting microphone must cause corresponding variations in the heat at the point of contact of the needle with the cylinder, and this again produces a mechanical movement of the pressing point, as well as of the air surrounding it, sufficient to give forth sound-waves. If such be the case the effect should be different for different metals, those answering best which have the lowest thermal conductivity and also the lowest specific heat. That this is really so is shown by substituting cylinders of other metals for the bismuth, all other things remaining the same. In this way I have compared lead, tin, iron, copper, carbon, and find that they all give forth the simple loose contact-sound when the cylinder is stationary, but that it is only with bismuth that there is any very great intensification of the sound when the cylinder is rotated. Now, by consulting the appropriate tables, I find that bismuth is a fraction lower than any other common metal in specific heat, while it is much below them all in thermal conductivity. This seems to bear out my explanation to a certain extent.

* Abstract of a paper read before the Royal Society of Edinburgh, by James Blyth, M.A., F.R.S.E., on May 3rd, 1880.

Money by Telephone.

"Say, miss," said a rather hard-looking customer to the young lady in charge of the central telephone office, one day last week, "say, miss, I'd like to talk with Mr. Joseph Snooks a moment."

The lady called Snooks and turned the instrument over to the guest.

"Hello, hello! Mr. Snooks!"

Snooks answered, and in the ensuing colloquy the lady could of course only hear the hard-looking customer.

"Snooks, old boy, I can't come up for that money to-day; I'm too busy."

"Eh?"

"No, can't get away."

"I know, but I'm sorry; I've got to meet Bmco about your affair."

"But I'd jeopardize all our interests. I positively can't come. Can you send the money down?"

"Down here."

"I don't believe she'll do it, will she?"

"No, I don't know her. She's a handsome girl with blue eyes and light hair. Know her?"

"I'll ask her about it. Wait, keep your ear there [aside, Mr. Snooks wants to pay me four dollars, and says for you to let me have the money. I'll ask again to make sure.] Snooks, did you mean for this fine young lady to pay me and charge it to you?"

"Don't hear you."

"Yes, yes, all right. [He says, miss, for you to take my receipts and let me have the cash. You are to put it in his telephone bill.] All right, Snooks, good-by, see you to-morrow," and he hung the mouthpiece on the hook.

"Fine fellow, Snooks," he continued, looking pleasantly at the manager. "I never heard of sending money by telephone before, did you?"

"No," responded the lady.

"Perhaps you haven't the change handy?"

"No," said she.

"You'll trust Snooks, I presume," he went on in a faltering manner.

"Certainly," she replied, "if he says to let you have it."

"You don't think the telephone would lie, do you?"

"Assuredly not. I'll just ask Mr. Snooks."

"No, no. He's a sensitive man; he wouldn't like to have so much fuss over a small amount. Make it two dollars and I will give him a receipt on account."

"I'll pay anything Mr. Snooks says. I'll call him."

"Rather than bother him again, I'll make it a dollar. Give me a dollar—"

"But I prefer to call him."

"Miss," said the man, "don't go near the wire now. There's a cloud coming up. You're going to be struck by lightning. Rather than that, I'd take fifty cents, a quarter."

"Oh! I'm not afraid," and she approached the instrument.

"Keep away from that wire!" he howled, "don't call Snooks. He might be struck. If you don't care for yourself, have some mercy on his family. You needn't pay the amount at all. I wouldn't risk Snooks for all the money in Brooklyn."

"I shall either call Snooks or a policeman," said the girl firmly.

"Make it a policeman and I'll go for him myself," shouted the tramp, as he jumped over the rail.

And then she called Snooks, who had been swearing at his end of the wire in the hope of making some one hear him, and told him it was all right, she hadn't quite paid the money.

Mountain Voice

WHEATSTONE'S MICROPHONE AND RADIOPHONIC RESEARCHES.*

By Alex. Graham Bell.

IN August, 1880, I directed attention to the fact that thin discs or diaphragms of various materials become sonorous when exposed to the action of an intermittent beam of sunlight, and I stated my belief that the sounds were due to molecular disturbances produced in the substance composing the diaphragm. Shortly afterwards Lord Rayleigh undertook a mathematical investigation of the subject, and came to the conclusion that the audible effects were caused by the bending of the plates under unequal heating. This explanation has recently been called in question by Mr. Preece, (p. 37, ante) who has expressed the opinion that although vibrations may be produced in the discs by the action of the intermittent beam, such vibrations are not the cause of the sonorous effects observed. According to him the aerial disturbances that produce the sound arise spontaneously in the air itself by sudden expansion due to heat communicated from the diaphragm, every increase of heat giving rise to a fresh pulse of air. Mr. Preece was led to discard the theoretical explanation of Lord Rayleigh on account of the failure of experiments undertaken to test the theory. He was thus forced, by the supposed insufficiency of the explanation, to seek in some other direction the cause of the phenomenon observed, and as a consequence he adopted the ingenious hypothesis alluded to above. But the experiments which had proved unsuccessful in the hands of Mr. Preece were perfectly successful when repeated in America under better conditions of experiment, and the supposed necessity for another hypothesis at once vanished. I have shown in a recent paper read before the National Academy of Science, that audible sounds result from the expansion and contraction of the material exposed to the beam; and that a real to-and-fro vibration of the diaphragm occurs capable of producing sonorous effects. It has occurred to me that Mr. Preece's failure to detect with a delicate microphone the sonorous vibrations that were so easily observed in our experiments might be explained upon the supposition that he had employed the ordinary form of Hughes microphone shown in Fig. 1, and that the vibrating area was

* A paper read before the Philosophical Society of Washington, June 11th.

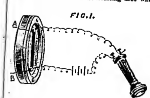

FIG. 1.

confined to the central portion of the disc. Under such circumstances it might easily happen that both the supports A B of the microphone might touch portions of the diaphragm which were practically at rest. It would of course be interesting to ascertain whether any such localisation of the vibration as that supposed really occurred, and I have great pleasure in showing to you to-night the apparatus by means of which this point has been investigated (see Fig. 2).

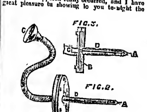

FIG. 3.

FIG. 2.

The instrument is a modification of the form of microphone devised in 1827 by the late Sir Charles Wheatstone, and it consists essentially of a stiff wire A, one end of which is rigidly attached to the centre of a metallic diaphragm B. In Wheatstone's original arrangement the diaphragm was placed directly against the ear and the free extremity of the wire was rested against some sounding body like a watch. In the present arrangement the diaphragm is clamped at the circumference like a telephone diaphragm, and the sounds are conveyed to the ear through a rubber hearing-tube C. The wire passes through the perforated handle D, and is exposed only at the extremity. When the point A was rested against the centre of a diaphragm upon which was focussed an intermittent beam of sunlight, a clear musical tone was perceived by applying the ear to the hearing-tube C. The surface of the diaphragm was then explored with the point of the microphone and sounds were obtained in all parts of the illuminated area, and in the corresponding area on the other side of the diaphragm. Outside of this area on both sides of the diaphragm, the sounds became weaker and weaker, until at a certain distance from the centre they could no longer be perceived.

At the points where one would naturally place the supports of a Hughes microphone (see Fig. 1) no sound was observed. We were also unable to detect any audible effects when the point of the microphone was rested against the support to which the diaphragm was attached. The negative results obtained in Europe by Mr. Preece may, therefore, be reconciled with the positive results obtained in America by Mr. Sumner Tainter and myself. A still more curious demonstration of localisation of vibration occurred in the case of a large metallic mass. An intermittent beam of sunlight was focussed upon a brass weight (1 kilogramme), and the surface of the weight was then explored with the microphone shown in Fig. 2. A feeble but distinct sound was heard upon touching the surface within the illuminated area, and for a short distance outside, but not in other parts. In this experiment, as in the case of the thin diaphragm, absolute contact between the point of the microphone and the surface explored was necessary in order to obtain audible effects. Now I do not mean to deny that sound-waves may be originated in the manner suggested by Mr. Preece, but I think that our experiments have demonstrated that the kind of action described by Lord Rayleigh actually occurs and that it is sufficient to account for the audible effects observed.

Eng. Mech. & World Science. July 8, 1881.

Nature July 28, 1881.

UPON A MODIFICATION OF WHEATSTONE'S MICROPHONE AND ITS APPLICABILITY TO RADIOPHONIC RESEARCHES[2]

IN August, 1880, I directed attention to the fact that thin disks or diaphragms of various materials become sonorous when exposed to the action of an intermittent beam of sunlight, [1] and I stated my belief that the sounds were due to molecular disturbances produced in the substance composing the diaphragm (Amer. Assoc. for Advancement of Science, August 27, 1880). Shortly afterwards Lord Rayleigh undertook a mathematical investigation of the subject, and came to the conclusion that the audible effects were caused by the bending of the plates under unequal heating (NATURE, vol. xxiii. p. 274). This explanation has recently been called in question by Mr. Preece (Royal Society, March 10, 1881), who has expressed the opinion that although vibrations may be produced in the disks by the action of the intermittent beam, such vibrations are not the cause of the sonorous effects observed. According to him the aërial disturbances that produce the sound arise spontaneously in the air itself by sudden expansion due to heat communicated from the diaphragm, every increase of heat giving rise to a fresh pulse of air. Mr. Preece was led to discard the theoretical explanation of Lord Rayleigh on account of the failure of experiments undertaken to test the theory.

He was thus forced—by the supposed insufficiency of the explanation—to seek in some other direction the cause of the phenomenon observed, and as a consequence he adopted the ingenious hypothesis alluded to above. But the experiments which had proved unsuccessful in the hands of Mr. Preece were perfectly successful when repeated in America under better conditions of experiment, and the supposed necessity for another hypothesis at once vanished. I have shown in a recent paper read before the National Academy of Science, April 21, 1881, that audible sounds result from the expansion and contraction of the material exposed to the beam, and that a real to-and-fro vibration of the diaphragm occurs capable of producing sonorous effects. It has occurred to me that Mr. Preece's failure to detect with a delicate microphone the sonorous vibrations that were so easily observed in our experiments might be explained upon the supposition that he had employed the ordinary form of Hughes' microphone shown in Fig. 1, and that the vibrating area was confined to the central portion of the disk. Under such circumstances it might easily happen that both the supports (A B) of the microphone might touch portions of the diaphragm which were practically at rest. It would of course be interesting to ascertain whether any such localisation of the vibration as that supposed really occurred, and I have great pleasure in showing to you to-night the apparatus by means of which this point has been investigated (see Fig. 2).

The instrument is a modification of the form of microphone devised in 1827 by the late Sir Charles Wheatstone, and it consists essentially of a stiff wire (A), one end of which is rigidly attached to the centre of a metallic diaphragm (B). In Wheatstone's original arrangement the diaphragm was placed directly against the ear, and the free extremity of the wire was rested against some sounding body, like a watch. In the present arrangement the diaphragm is clamped at the circumference like a telephone-diaphragm, and the sounds are conveyed to the ear through a rubber hearing-tube (C). The wire passes through the perforated handle (D), and is exposed only at the extremity. When the point (A) was rested against the centre of a diaphragm upon which was focussed an intermittent beam of sunlight, a clear musical tone was perceived by applying the ear to the hearing-tube (C). The surface of the diaphragm was then explored with the point of the microphone, and sounds were obtained in all parts of the illuminated area and in the corresponding area on the other side of the diaphragm. Outside of this area, on both sides of the diaphragm, the sounds became weaker and weaker, until at a certain distance from the centre they could no longer be perceived.

At the points where one would naturally place the supports of a Hughes microphone (see Fig. 1) no sound was observed. We were also unable to detect any audible effects when the point of the microphone was rested against the support to which the diaphragm was attached. The negative results obtained in Europe by Mr. Preece may therefore be reconciled with the positive

Notes.

A CURIOUS phenomenon has been observed on a property at Vernon, in France. Some five or six years ago, a garden planted with cherry-trees and gooseberry bushes was struck with lightning, a deep hole, about 10 centimetres in diameter, being made in the ground. Subsequently, everything died about the hole, the death circle becoming larger every year. It is now stated to be 7 metres in diameter, and has just reached a cherry-tree planted twelve years' ago, whilst some replanted gooseberry-bushes died in two years. The part the lightning has played in producing the phenomenon has not as yet been explained.

Tel Journal. Mar 15 75

New Lightning Protector for Telegraph Lines (Lemasson System).—Among the different lightning protectors invented to protect telegraph lines, one of those most used is formed of two plates furnished with points and insulated from each other, one plate being traversed by the line current, and the other placed in communication with the earth. So long as atmospheric electricity is moderate the current goes through the first plate only, but when excessive it runs to earth through the points and the second plate. M. Lemasson proposes to render such a lightning protector of greater efficiency. He places a tube inside a conducting mass, provided with 100 transverse striates, and in immediate contact with earth. A cylinder communicating with the line occupies the centre of the tube, but does not touch it, and is provided with 40 longitudinal striates. By reason of the different direction of the striates, 4000 crossings are obtained,—uniformly distant ½ a millimetre from each other,—and these crossings may be regarded as so many points. Hence, although measuring only 1 decimetre in length by 4 centimetres wide and broad, M. Lemasson's arrangement, though much smaller, is more efficient than that in ordinary use. An important addition to the apparatus is the insertion of a pipe (furnished with a stop-cock) to the air-space between the "tube" and the "conducting mass," so as to rarefy the air, and thereby diminish the resistance offered to the discharge of excessive atmospheric electricity.

BEECH TREES AND LIGHTNING.—It is a popular belief that lightning will not strike a beech tree. During a thunder-shower at Goshen, Mass., a beech and maple standing close together, received the electric bolt, which shattered the maple and passed into the earth through a prostrate hemlock tree lying near, which was stripped of its bark nearly the whole length. No trace of the lightning was left upon the beech.

The simple reason of this is that beechwood is not as good a conductor of electricity as other kinds of wood, for instance maple, and the lightning or electricity will of course always select the best conducting path to the earth. M. B. 1876

7

CENTRAL TELEGRAPH STATIONS.

THE great commercial capitals of the world, London and New York, have, within a very short period, been provided with Central Telegraph Offices which for extent and completeness are unequalled elsewhere. The Central Telegraph Station in St. Martin's-le-Grand, and the new offices of the Western Union Telegraph Company in Broadway, New York, may be regarded as evidences of an amount of progress such as has attended few institutions in our time. Less than thirty years ago the "system" of the late Electric Telegraph Company—or, to speak more correctly, the telegraphic system of the United Kingdom—consisted of a line to Nine Elms, and a small office at 334, Strand. Similarly, in 1846, a single wire was erected to an obscure office beneath the express offices at No. 16, Wall Street, New York, and two wires from Washington terminated in a small room over the Ferry-house in Jersey city, where three clerks easily—and not very continuously—performed the whole telegraphic business of the city of New York. We need not trace the progress of the Electric Telegraph Company eastwards until it acquired extensive offices,—first, in Founders' Court, Lothbury, and subsequently in Telegraph Street, Moorgate Street. Nor need we do more than simply mention the British and Irish Magnetic Telegraph Company, with its offices in Threadneedle Street, and the United Kingdom Telegraph Company, located in Gresham House. All three were eventually housed in the premises built by the Electric Company in Telegraph Street, and thence the next move was to the new Post-Office in St. Martin's-le-Grand. This event occurred on the 17th of January, 1874; and little more than a year afterwards—viz., on the 1st of February last—the Great American Telegraph Company moved to its new premises in Broadway, New York.

The American structure has been erected at a cost of more than two million dollars, and a considerable portion of this amount has been subscribed in England—chiefly in London, we believe. It is built of brick and granite, in what, with some latitude, may be designated as the French Renaissance style, the main idea in its construction being to reduce in appearance—by the proportions and the arrangement of the details—the great height of the building, as compared with its width or front. The building is said to be fire-proof throughout, wood having only been used for the doors, window-sashes, and the wainscoting. Most people are familiar with the appearance of our new Post-Office buildings in St. Martin's-le-Grand. Many regard them as being

[illegible] of the Meteorological Society, has done good service in reading an exhaustive and able paper on the subject before the Society of Arts, and an admirable notice was given of it in the *Times*. Dr. Mann has supplemented this notice with an excellent letter to the leading journal on the precautions to be taken, especially with the tall zinc tubes now so largely used for chimney-tops. Mr. Preece had previously called attention, in the *Times*, to the danger of chimneys, lined as they are with soot, filled with ascending currents of heated air and smoke, and terminated

Notes.

A curious phenomenon has been observed on a property at Vernon, in France. Some five or six years ago, a garden planted with cherry-trees and gooseberry bushes was struck with lightning, a deep hole, about 10 centimetres in diameter, being made in the ground. Subsequently, everything died about the hole, the death circle becoming larger every year. It is now stated to be 7 metres in diameter, and has just reached a cherry-tree planted twelve years' ago, whilst some replanted gooseberry-bushes died in two years. The part the lightning has played in producing the phenomenon has not as yet been explained.

Tel Journal. Mar 15 75

New Lightning Protector for Telegraph Lines (Lemasson System).—Among the different lightning protectors invented to protect telegraph lines, one of those most used is formed of two plates furnished with points and insulated from each other, one plate being traversed by the line current, and the other placed in communication with the earth. So long as atmospheric electricity is moderate the current goes through the first plate only, but when excessive it runs to earth through the points and the second plate. M. Lemasson proposes to render such a lightning protector of greater efficiency. He places a tube inside a conducting mass, provided with 100 transverse striates, and in immediate contact with earth. A cylinder communicating with the line occupies the centre of the tube, but does not touch it, and is provided with 40 longitudinal striates. By reason of the different direction of the striates, 4000 crossings are obtained,—uniformly distant ¼ a millimetre from each other,—and these crossings may be regarded as so many points. Hence, although measuring only 1 decimetre in length by 4 centimetres wide and broad, M. Lemasson's arrangement, though much smaller, is more efficient than that in ordinary use. An important addition to the apparatus is the insertion of a pipe (furnished with a stop-cock) to the air-space between the "tube" and the "conducting mass," so as to rarefy the air, and thereby diminish the resistance offered to the discharge of excessive atmospheric electricity.

BEECH TREES AND LIGHTNING.—It is a popular belief that lightning will not strike a beech tree. During a thunder-shower at Goshen, Mass., a beech and maple standing close together, received the electric bolt, which shattered the maple and passed into the earth through a prostrate hemlock tree lying near, which was stripped of its bark nearly the whole length. No trace of the lightning was left upon the beech.

The simple reason of this is that beechwood is not as good a conductor of electricity as other kinds of wood, for instance maple, and the lightning or electricity will of course always select the best conducting path to the earth. Feb 8. 1876

THE TELEGRAPHIC JOURNAL.
Vol. III.—No. 55.

LIGHTNING.

There are indications that we may anticipate severe electrical disturbances during the coming summer. The winter has been unusually long and severe. Abnormal weather has occurred over most parts of the globe. Reports of severe thunderstorms reach us from the Cape and the antipodes. Exceptional conditions of this kind abroad usually presage similar conditions in England. "Coming events cast their shadows before." But whether the coming summer be above or below the average in lightning accidents, we are none the less bound to call attention to the fearful apathy and gross carelessness evinced in protecting buildings from atmospheric electrical discharges.

During two severe storms in England, in June, 1872, there were ten deaths and fifteen cases of injury to human beings; sixty houses struck, and fifteen burnt down; and twenty-three horses or cattle, and ninety-nine sheep, killed. Those accidents that are not recorded are innumerable. In large towns damage to property is more frequent than destruction of human life, but in the open country destruction of life is perhaps more frequent than destruction of property, unless we except trees, which are ruined in thousands every year, and unfortunately—from their size and growth—the finest suffer.

Lightning protection is therefore not only a necessity, but it is a source of satisfaction and comfort. It is difficult to comprehend the reasons why it is not more largely adopted. It is not its inutility—for the beneficial effect of lightning-conductors amongst our buildings and our shipping is incontestible. It is not its expense—for a house can be protected for a less sum of money than is required to bed out a parterre. It is not its difficulty—for any skilled workman or energetic landlord can do it with ease.

Dr. Mann, the President of the Meteorological Society, has done good service in reading an exhaustive and able paper on the subject before the Society of Arts, and an admirable notice was given of it in the *Times*. Dr. Mann has supplemented this notice with an excellent letter to the leading journal on the precautions to be taken, especially with the tall zinc tubes now so largely used for chimney-tops. Mr. Preece had previously called attention, in the *Times*, to the danger of chimneys, lined as they are with soot, filled with ascending currents of heated air and smoke, and terminated in grates, acting as lightning-conductors. If all such chimney-pots be connected with the water-pipes by galvanised iron ropes, and if all these pipes make good earth, a house is as safe from lightning as a collier in a mine.

All lightning-protectors should be constructed on proper scientific principles, and we have published in our columns many valuable papers on the subject. The great desiderata to be urged are—the employment of perfectly continuous metallic ropes or rods, the use of good earths, and the termination of the conductors in the air in points. A great fact to be remembered is, that joints, and earths, and points deteriorate, and lose their efficiency: they therefore require frequent examination and frequent renewal. Lightning-conductors require annual inspection and careful overhauling.

It is needless to point out to telegraphists the necessity of a good earth, for they all know that their circuits are unworkable without them; but it is lamentable to see the condition of the earths to the lightning-protectors of the steeples of some of our cathedrals and churches. The splendid new spire of Llandaff cathedral is positively in a dangerous condition from this cause. Nine out of every ten churches are in the same condition. Earth-wires are plunged into the interior of cisterns; they are leaded into stones; they are bedded in dry sand. One was carefully put into a glass bottle buried in the dry earth; another was coiled carefully into the interior of a wooden pail, in the basement floor of the house it was meant to protect. Every case of the inefficiency of lightning-protectors that has been examined has been proved to be due to the existence of such gross ignorance of the commonest principles of electrical science as is evidenced by the above cases.

The country is now overrun with telegraphs. Telegraphists are to be found everywhere. There is no difficulty in securing the advice and assistance of skilled men, and our churchwardens and church dignitaries would do well to call such experience to their aid. It is better to lock the stable door before the steed is stolen.

INFLUENCE OF ELECTRICITY ON EVAPORATION.—M. Mascart has just communicated the results of his experiments on this subject to the French Academy of Sciences. Since atmospheric electricity has been known to exist, it has been supposed to owe its origin chiefly to the evaporation of water, and the experiments of Pouillet seemed to prove this supposition to be true. But more recent researches have cast doubts upon it. It was observed that in all the cases of violent ebullition in which electricity was developed by evaporation, there was always to be found small grains of solid matter projected upon the walls of the vessel; and these appear to have played an important part in the production of electricity, for, when care was taken entirely to exclude them, no electricity was produced. Again, the quantity of electricity furnished by gentle evaporation, was very feeble and inappreciable. M. Mascart's experiments had an opposite aim. They were intended to determine if electrification modified the evaporation of water. Accordingly, he arranged a set of small basins, containing water, or moist earth, under the conductors of a Holtz electrical machine, maintained at a high and constant potential. The basins themselves were connected to earth, as also were the other poles of the machine. The electrified conductors over the basin were in the form of a grating, which did not check evaporation, and were supported about 2 centimetres over the evaporating surface. The quantity of water evaporated by each basin was determined daily. M. Mascart found that electrification of the conductors accelerated the rate of evaporation whatever the sign of the electricity, and in some cases it doubled the rate. He also found, however, that slight variations of temperature completely masked the electric influence, and concordant results could only be obtained in a closed box regularly dried and kept in a cellar, where the temperature only varied from 4° to 6° during nearly a month. M. Mascart did not clearly determine the rates of evaporation under positive and negative charges; but he continues his experiments. However this curious effect of electricity be brought about, it seems to be appreciable only under very high charges. In connection with it, we may refer to the experiments of Mr. Cassamajor on the motions of camphor in electrified water, see TELEGRAPHIC JOURNAL, Dec. 15, 1877.

Tel Journal June 1.77

PROFESSOR LOOMIS, of Washington, who has closely studied electrical phenomena, claims to have communicated with an assistant twelve miles away, by means of an aërial current. The current was reached by flying kites a certain height at each point, the string used being a copper wire. When both kites had attained high altitudes, messages were sent and received at the distance mentioned by an instrument at the ground end of the wire, the only electro-motor being the atmospheric current between the kites.

DIMENSIONS OF LIGHTNING RODS.—The following results are published by Dr. Nippoldt of the Observatory of Paris. The existing errors with regard to the proper dimensions of lightning-rods are traceable to Kuhn's *Encyclopædia of Physics*, which gives the thickness for a conductor of iron 64 feet long as half an inch, and states that for other metals, such as copper or lead, the section ought to be proportional to the resistance of the metal.

The lightning conductor ought to fulfil two conditions:

1. To draw the current to earth.
2. To have sufficient sectional area to lead away the discharge without an injurious rise in temperature.

The elevation in temperature depends on the intensity of the current and the conductivity of the rod. Let W be the heat developed, J the intensity of the current, R the resistance of the rod; then

$$W = J^2 R. \quad (1)$$

Again, let l be the length of the conductor, g the cross-section to be found, s the density of the conductor, w its specific heat, r its specific resistance, M its mass, and t the temperature; then from the electro-dynamic law it follows that

$$R = \frac{l}{g} r \quad (2)$$

and

$$W = J^2 \cdot \frac{l}{g} r \quad (3)$$

and the mass M, which receives the total heat W, is raised to the temperature

$$t = \frac{W}{Mw}. \quad (4)$$

and as $M = lgs$, by substituting this value in equation 4, we have

$$t = \frac{W}{lgsw} = \frac{J^2 \cdot r}{g^2 sw} \quad (5)$$

Temperature is independent of the length of the rod. The four metals employed as lightning conductors are

Metal.	Specific Heat.	Density.	Resistance.
Iron	0·1138	7·75	0·0986
Copper	0·0951	8·95	0·0162
Lead	0·0314	11·35	0·0199
Platinum	0·0324	21·54	0·0918

An iron conductor of 144 square millimetres ought therefore to be equalled by a copper conductor of 90 square mm., by a lead one of 320, and a platinum one of 156. M. Kuhn's gives the corresponding dimensions as 24 for copper, 230 for lead, 134 for platinum.

The resistance of copper (0·0162) given above is on the supposition that the metal is chemically pure. According to Dr. Mathiessen, the resistance is tripled if the metal contains ½ per cent. of iron. It is necessary to use copper containing not more than 2 per cent. of iron, and giving only one-fifth of the resistance of iron—that is, 0·0197 resistance instead of 0·0162.

The end of the rod should terminate in a platinum point two or three millimetres thick, having from three to seven square millimetres of section. A platinum point of this size will be heated from 2,000 to 500 times more than the rod itself, and if the passage of the current raises the temperature of the rod only 4° C. the platinum point will melt.

Tele Jnl Sept 15.78

ATMOSPHERIC ELECTRICITY AND PLANT LIFE.—According to M. Grandeau, atmospheric electricity is a powerful agent in the process of assimilation amongst vegetables. He says that plants defended from its influence have built up fifty or sixty per cent. less of living (azotic) matter than those exposed to ordinary conditions. The proportion of ash is higher, and that of water lower, in plants sheltered from the action of atmospheric electricity. The electric screen enclosing the plants experimented on was formed of four triangles of iron. The plants were maize, tobacco and wheat; all other conditions were the same, but of the two specimens pitted against each other one was screened from atmospheric electricity and the other was not. The plants after being allowed to grow for several months, were then measured, weighed and analysed. All the experiments exemplify the above percentage in the most striking manner. The plants tested are tall, but low growing plants are equally influenced by atmospheric electricity. This fact may help to explain the absence of herbs under certain trees. It should also be mentioned that the total development of the plant is proportional to that of the azotic matter, as in growth, under normal conditions. M. Berthelot, in a subsequent note to the Academy on this subject, draws attention to the discovery made by him that free nitrogen united itself to organic matter under the action of electric currents not only from ordinary induction coils, but from feeble voltaic batteries; for example, five Leclanché cells: the proportion of nitrogen thus fixed in seven months on paper and dextrine being 1·92 thousandths, which will represent about 1·2 hundredths of matter analogous to the nitrogenised compounds of vegetables. It would thus appear that the slow, continuous action of feeble atmospheric currents on vegetation has a far more important bearing on agriculture than the formation of nitrous and nitric acid with their ammoniacal salts by the violence of the lightning flash.

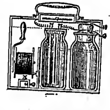
M. GRANDEAU, in a subsequent note to the French Academy, has supplemented the results given in the last note. By aid of a Thomson quadrant electrometer and water-dropping collector, he has measured the electrification under and in the neighbourhood of those large sheltering trees and bushes which appear to impoverish the soil beneath them. He finds that the potential beneath these trees is *nil*, while there is a sensible positive potential beyond the area which their foliage shelters. These experiments of M. Grandeau show that it is not want of moisture, light, or heat alone, but want of electricity also, which renders the shade of dense trees so inimical to herbs and undergrowth.

Tel Journ Nov 1.76

A GALVANOMETER FOR TESTING LIGHTNING-CONDUCTORS.

THE preliminaries necessary to testing lightning-conductors are often troublesome, the apparatus required for it being rarely obtainable in handy and convenient form, though, indeed, little apparatus is required; merely a galvanic element, a galvanometer, and a sufficient quantity of insulated copper wire. The firm of Mitteistrass Gebrüder, in Magdeburg, have recently combined the essential parts in a galvanometer chest the arrangement of which (described in a recent number of *Dingler's Polytechnisches Journal*) is as follows:—In front the lid is fastened with two hooks. At the side are two binding screws

9



for attachment of copper wires. On the top is a sensitive galvanometer, the needle of which can be arrested with a screw. In the interior of the chest stand two glasses (see fig.), with equal width of neck, so that the glass-stopper in one may be readily transferred to the other, so as to close it. In the one glass is a suitable solution of bichromate of potash; in the other is the carbon and zinc element, from which spirals of wire proceed to the binding-screws as indicated. It is easy to lift the element out of the empty glass into the one filled with liquid, and so produce a current. In the third division of the chest is a roller with silk-covered copper-wire, which can be easily wound off, and, with the aid of a small handle, wound on again. Lastly, a binding screw serves for connecting the line to the wire-rope of the lightning-conductor.

Where desirable, the arrangement is so completed that only one turn of the conducting wire round the galvanometer needle is inserted, or all the turns; which can be done in a moment by turning a binding eye on the upper side of the chest. Lastly, on the under side of the lid may be introduced two resistance-coils of 1 to 10 Siemens' units, which, again, may be similarly inserted or excluded.

In testing a lightning-conductor the process is as follows:—1. The wire is unwound from the roller, drawn up to the roof, and the end of it wound about the point of the conductor. 2. The chest is opened, the element lifted over into the salt solution, the chest closed again, and so placed that the needle is still; then the binding-screw of the roller is connected with that of the chest with a piece of wire. 3. By means of the small binding-screw in the bottom of the chest a wire is connected with the lower part of the wire-rope of the lightning-conductor, and is brought to the second binding-screw of the chest. If there be perfect electric connection between the upper point of the conductor and the lower parts, the needle will be deflected. Should the deflection not occur, the place of interruption is sought for by connecting the lower binding-screw with the wire at successively higher points. 4. For investigation of the earth-conduction, the point of the lightning-conductor is excluded, by detaching the wire and connecting it with a neighbouring gas-chandelier, an iron spring, or an iron rod forced deep into the ground, and then the circuit is completed as before. The deflection of the needle will be greater, the more perfect the earth-conductor. Important advantage is here derived from the above-mentioned arrangements for insertion of the resistance coils, or only one or the whole of the galvanometer windings. After use, the element is lifted back out of the solution into the empty glass, and the galvanometer needle again arrested.

Note on M. Ducretet's Rheotome, with Constant Direction. By M. Carl.

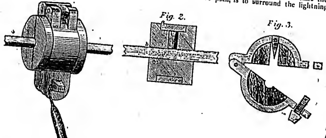
M. Ducretet lately called attention to the resistance to passage of a current by aluminium forming the positive electrode of a voltameter; and thought the property might be utilised in telegraphy. M. Carl finds from experiment that the stoppage of the fluid by aluminium is not constant every moment, and the metal has not the *rôle* of a completely hermetic valve. Hence he does not see how the liquid rheotome can facilitate the problem of simultaneous transmission, or working of apparatus based on use of two currents. But it might replace with advantage the call by inversion of current used at all stations worked by derivation from the same wire. It would be more economical, and would isolate almost completely the station which had not to receive the call (so that weaker batteries might be used). By interposing the rheotome between the lightning conductor and the line, the consequences of derangement in bobbins of such apparatus would be considerably diminished.

Tel. Jnl. Mar 1 76

DESCRIPTION OF A LIGHTNING PROTECTOR ESPECIALLY ADAPTED FOR AERIAL LINES.

By J. R. Vaes.

A ring of metal (fig. 1) about 1½ centimetres wide, and 2½ centimetres in diameter, is cut in two. On one side the two halves are held together by means of a hinge, and on the other side they shut by means of a screw. This ring encircles a bobbin



of hard wood, also cut in halves, and bored through its axis. The raised edges of this bobbin prevent the metal ring slipping off. In the interior of the ring is fixed a protecting point of aluminium, bronze, or platinum, which extends within a distance of one or two millimetres of the groove in the bobbin (figs. 2 and 3).

To apply the protector to a telegraph wire, the ring, and with it the two halves of the bobbin, (fig 3) are opened and placed on a wire of the same gauge as the groove in the wood. The ring and the bobbin are then closed with the screw, care being taken to pass under the head of the screw a copper wire covered with guttapercha, the other extremity of which is connected with a plate of metal attached to the bottom of the post, and making a good earth connection.

The lightning protector following all the vibrations of the wire, it is impossible that there can be a contact between the wire and the protecting point, and the point itself is excluded from atmospheric influences.

Remarks.

1. The diameter of the groove in the bobbin should be slightly smaller than that of the wire to which it is intended to be fixed.

2. To fill up the chinks that will always exist to a greater or less extent between the two halves of the bobbin, it is sufficient to introduce, before fixing to the wire, a thin layer of guttapercha or tarred cloth; these substances giving way to the pressure, fill up the chink entirely.

3. In case of rain, the lightning protector might give rise to derived circuits, owing to the short distance between the exterior of the metallic ring *a*, and the wire *b* (fig. 2). Several methods suggest themselves to remedy this defect. It would be insufficient to apply a coat of varnish to the metallic parts, it would therefore be better to lengthen the bobbin so as to increase its length on either side of the ring, or even to heighten the edges of the bobbin.

Another method consists in covering the wire with an insulating material for a distance of some centimetres on each side of the protector. That which appears the simplest, and at the same time the most effective plan, is to surround the lightning protector with a covering, thus removing it from the influences of rain. Owing to its small dimensions (the protector can easily be covered with the hand), the application of this last suggestion would not be difficult.

14

[20216.]—Ten-inch Plate Machine.—Base, 20 × 10 × 1¼ thick; supports of broomstick well varnished. The axles of the plate are cemented on, and each has a small steel piece to run in brass bearings, which are screwed to the top rail. One of the axles has a wheel 1¼ diameter turned on it, and the bottom rails carry a multiplying wheel about 5in. diameter. The rubbers are 2¼ × 1¼, stuffed with cotton-wool, and covered with chamois leather. They are carried by two pieces of mahogany, 3-16 thick, 6in. long, in which are drilled holes rather larger than the cross-piece which carries them. They are screwed to a piece of wood placed between them, which should be slightly smaller than the thickness of the two rubbers and the plate together. A wedge between this piece of wood and the cross-piece keeps all firm when working; a nut and bolt about halfway regulates the pressure. My conductor was made after the Winter model—wood ball, 5½in. diameter with 1¼ brass ball projecting, fixed on a glass tube in a stand. This is separate from the machine, which is a disadvantage, but a cramp should be used to fix machine to the table. The collectors are made of three pieces of broomstick covered with tinfoil, and screwed together, one on each side of the plate. The ends should be rounded off, not covered with tinfoil, but some insulating cement, and connected to the ball by an iron rod. Brass tube is much the best to use for conductors on account of its strength and lightness. Solid metal bodies are no better conductors than hollow ones, as the electricity keeps entirely on the surface. In making an electrical machine I should advise "Economical" to keep as near to the Winter machine model as he can, as I consider it much superior to any other.—Owl.

Killed by Lightning.

[Philadelphia Press.]

Henry Davis, a colored laborer, was struck by lightning and instantly killed Monday afternoon while sitting in a chair in his brother-in-law's house, No. 1,710 Philip street. The house is a three-storied brick building and occupied by Henry Stevenson and his family. Davis, in company with his wife, had been paying a visit, and the group were all seated in a room on the first floor facing the street. Davis was in a chair tilted back against the wall between the door and the open window. About 5.30 o'clock rain began to fall, and the lightning was so severe that Stevenson got up to close the window. Just as he was about to return to his seat a vivid flash of lightning almost blinded him, and a loud report was heard simultaneously with the flash. The window frame was torn loose, and the plaster from the ceiling to within two feet of the door was scattered and thrown down. A bluish, sulphurous smelling smoke filled the room, and when the frightened brother-in-law started to open the door he heard Davis exclaim: "Lord! what's that?" and noticed that his eyes were fixed on vacancy, and that a pipe which he had been smoking was lying on the floor. For a moment the whole party was so stunned by fright that not a word was uttered. The wife ran over to her husband and lifted one of his hands, but it fell limp and lifeless. He was dead.

ELECTRICAL LIFE TEST.

Jan 77

It is a well known fact that muscles contract under the influence of electricity, and it is long since experiments were first made in the stimulation of dead bodies by this means. Some curious phenomena have been obtained in this way. Recently, Dr. Kappeler, of the hospital of Münsterlingen, has added some new observations on the subject. He subjected twenty corpses to the action of various electric currents, and noted the rate of disappearance of the electric muscular contractility. In persons emaciated by long chronic maladies, this disappeared much more rapidly than in robust individuals, or those who had had acute maladies. It disappeared five quarters of an hour after death, at the quickest, and six and a half hours at the slowest. It is in cases where a rise of temperature is observed after death (which are not extremely rare), that the electric contractility persists longest. The importance of this sign of death is evident if we reflect that the contractions under electricity continue intact so long as there remains the least life. In the most prolonged faints, in the deepest lethargies, in all the varieties of apparent death, poisonings by carbonic oxide, chloroform, or narcotic substances, this valuable sign can be had at will, so long as real death is not a *fait accompli*. The fact of death can ...

[March 17, 1877.

EXPLOSIONS ON LIGHTNING ROD POINTS.

It is a well known fact that, if a metallic point communicating with the earth be presented to the conductor of an electric machine charged with positive electricity, the angle of the electroscope of the apparatus becomes small. The reason is that negative electricity escapes from the point as soon as developed, and serves to neutralize a quantity of the positive electricity of the conductor, no spark being produced. This phenomenon, as Professor Stroumbo, of the University of Athens, points out, is produced differently when the Holtz electric machine is used. If, while sparks are passing between the two balls of the apparatus, a third ball, having a metallic point attached to it, be taken in the hand and moved nearer one of the fixed balls, when the intervening distance becomes so small that the negative electricity of the point may escape the sparks at once cease. Yet, if the point be removed, they begin passing again between the two balls. This experiment can be repeated indefinitely. Now if the distance between movable and fixed balls above mentioned, at which no sparks pass, be gradually augmented, at a certain stage sparks will reappear between point and fixed ball. The conclusion from this is that, if the negative electricity of the point has great intensity, sufficient to enable it to escape from the point and pass over the interval, there will be no spark between point and fixed ball; but if the negative electricity of the point has not intensity sufficient to cause it to escape as soon as developed (the attraction then diminishing inversely as the square of the distance), there will be an explosion on the point itself, and electric sparks will occur constantly between the point and fixed ball, just as between the two balls of the machine.

During storms, the atmosphere is charged with enormous quantities of electricity, which, however, in their action should follow the same law as the smaller quantities produced in electric machines. If then a cloud, having positive electricity in determinate quantity, passes not too far away from the lightning rod point, analogous effects will take place. Then electricity developed by induction on the lightning rod will continue to escape at the point as soon as it gets there, and will go to neutralize the positive electricity of the cloud, neither thunder nor lightning being produced; but in case the same cloud were placed too far away, according to the experiments above detailed, an explosion might follow at the point of the rod, an intense heat would be developed, and the platinum point of the rod would be fused. This phenomenon occurred at the Royal Palace of Athens, where the platinum point was found melted, as shown in our illustration, which represents the rod in its full size.

POINTED LIGHTNING RODS.

The important question as to the proper form of lightning rods occupied the minds of many savants some 75 years ago, and filled part of the scientific journals of that period. It has lately been renewed, and, as formerly, there are defenders and antagonists of the pointed rods. It is argued by the latter that the object of a lightning rod is not to attract the thunderclouds to the building to be protected, and induce discharges there; and it is claimed that long, upward-projecting lightning rods do this very thing, and that, although they are a protection in one sense, giving a ready path to the discharges, they become a source of danger by attracting the electrically charged clouds, and making discharges more frequent. Let us test this reasoning by the well known laws of electricity.

The amount of electric attraction depends on the extent of the attracting surfaces, and on their distance. If a series of clouds, say of a square mile in extent, floats over the earth's surface, these clouds being charged with positive electricity, they will induce, in that part of the earth's surface within the attractive influence, negative electricity. This charge will increase as the distance decreases, as the clouds follow the direction of the attraction; until at last, when the distance becomes small enough, an explosive discharge takes place, the stroke of lightning consisting in the simultaneous discharge of positive electricity from the cloud to the earth, and of negative electricity from the earth to the cloud. The manifestation of light and heat is the simple result of the neutralization of the two electricities, and will be greater in proportion as their quantity and intensity were greater.

Looking at the subject exclusively from this point of view, all that appears necessary is to provide a ready path to the electric discharge, such as a rod made of good conducting material, of sufficient capacity to be uninjured by the strongest current, and well connected with the ground, so as to establish at the moment of discharge a perfect communication between the cloud and the earth, which, previous to the stroke of lightning, were charged with opposite kinds of electricity. If we consider the function of elevated points on lighting rods, we find that Benjamin Franklin was correct when he recognized the gradual absorption or discharge of electricity as the main duty of lightning rods. Projecting points do not attract [illegible] thunderclouds; but elevated portions of the ground, as well as trees and houses, when in conducting communication with the earth, become charged by induction, and then exert attraction, whether there are pointed rods in the vicinity or not. The latter will, by their property of silent gradual discharge, serve to diminish the electric tension; and in place of being a source of attraction they will diminish this attraction, and take from the impending discharge a great deal of its violence.

We must, therefore, come to the conclusion that elevated points are desirable as upper terminals of lightning rods; and experience fully verifies this conclusion by practical results. One of the oldest instances took place in the tower of the cathedral of Siena, in Tuscany, which had been very frequently damaged by lightning. In 1776, a lightning rod was erected; but the people objected, and some of the priests called it an impious contrivance, invented by a heretic; but when it was found that the tower was rarely struck, and that once during a heavy thunderstorm the stroke followed the lightning rod without doing the least damage, the heretical contrivance came into proper esteem. The starlike terminations of some lightning rods are injurious. Faraday has proved that a single point discharges and absorbs electricity faster than a bifurcated or trifurcated terminal; if more points are added, still slower becomes the discharge, by their mutual interference; until at last, when the top is surrounded with an infinite number of points, a ball is the result, and the silent discharge ceases altogether.

But the upper pointed terminal is not the main part of the lightning rod; because it may be omitted altogether, although it is better to attach it. The main part is the ground connection; and as this is out of sight, it is often shamefully neglected. Much ignorance prevails in this respect also; hence it frequently happens that the electric current leaves the rod, to enter the house and pass off by the gas, water, or sewer pipes; and in its course it sometimes causes considerable damage. A connection with a water course, a well (not a cistern), or at least with the moist ground, is not imperatively necessary. If the soil is silicious and naturally dry, it is best to drive some pointed iron bars into the ground in such places as they are most likely to reach moisture, and connect all their upper ends with the conducting rod. The rule that requires a conducting surface equal to that of the roof to be protected, to be buried in the ground, given by some would-be authorities, has no foundation either in theory or practice. It is not the electric charge of a roof which has to be disposed of, but that of a cloud over it; and the latter has sometimes an extent of several square miles. All reported failures of lightning rods may be traced to defective connections, especially ground connections. Rods that are faulty from the outset are often made useless by subsequent neglect: as we found some years ago at the village of Gilboa, Schoharie county, N. Y. The church was situated on a hill, and quite exposed; the under end of the lightning rod, which in its upper end was connected with the spire, was pulled out of the ground, and lay on a pile of firewood in the rear of the church. If this church had been struck and burnt down, it might have been pointed out as an example of the utter uselessness of lightning rods.

A PARIS CHURCH DAMAGED BY LIGHTNING.—The little Gothic church of Kernascleu in the commune of Saint-Carné-Tregomel, built by Alain de Rohan in the fifteenth century, was lately nearly totally destroyed by lightning. The steeple was struck and fell through the roof, crushing in its fall fretwork and pinnacles, and doing much damage to the sculpture in the interior.

TRANSMISSION OF OBSERVATIONS IN TIMES OF THUNDERSTORM.

The establishment of a meteorological observatory on the summit of Puy-de-Dôme, and its telegraphic connection with the observatory of the plain, situated at Clermont Ferrand, have enabled M. Germain (says *Les Mondes*) to make, during very violent thunderstorms, tests as conclusive as interesting, as to the efficacy of the lightning-conductors used in telegraphy.

1. Those with multiple points would be at a maximum of efficacy, if, instead of consisting of two rectangular plates furnished with points arranged parallely, they were composed of two bands in spiral, so that the line and the earth might be opposite and in presence of each other over a large extent by means of the points.

2. Those based on the calorific properties of electricity are dangerous by reason of the frequent isolations resulting from fusion of the wire, or the bad communications which too delicate mechanisms form inopportunely with the earth. Thus, the telegraphic receivers are sometimes put out of use, the operators struck with lightning, and the line rendered useless at the moment most indispensable for the exchange of correspondence. The putting of the line to earth being the only state of inoffensive electric discharge, M. Germain first experimented with an instrument which realises this automatically at each lightning discharge, and restores the other state immediately after. These arrangements are simple and ingenious. Whereas, in the direct discharges, the protecting wire, breaking, allows a certain quantity of fluid to escape to earth; in the discharges by introduction, the movement is so rapid, that the wire has no time to redden and break.

Several leaves of gold were arranged on a metallic frame connected with the line, at a very small distance from each other, so that the fluid, reaching the extremity of the leaves, made them repel each other. This separation being made as small as possible, the line was connected to earth. The same powerlessness to prevent the passage of the fluid by introduction, through the telegraphic receiver, was demonstrated. Moreover, the heat of the leaves injured their elasticity.

M. Germain more successfully employed a system of coils, with three or four spirals of thick wire wound on a cubic centimetre of soft iron. A light armature connected with the line, and communicating now with the receiver, now with the earth directly, is attracted during the strong discharges. This system of coils, however, with differential action relatively to the ordinary coils of telegraphs, was found at fault. In a violent thunderstorm it happened that there was not enough electric quantity to produce the magnetisation, and that there was enough of potential to burn the fine wires of the telegraphs.

To suppress all these inconveniences, it was necessary to arrange that the line should be permanently in direct communication with the earth, and that the exchange of correspondence should take place all the same. This M. Germain realised. In the first coils he experimented with, each row of spirals of wire of the same size was connected, on one hand, with the line, and on the other, with the earth, so that the current branched into twenty spirals, where it passed in quantity, which was greater the smaller the spirals. The smallest spirals were found to be precisely the most influential by their proximity. The effects obtained by this system, on a short line, well insulated, showed a powerful magnetic force.

For longer lines, where derivations can be had, the coils employed are formed as follows:—Round a cylindrical sheet of very thin, soft iron, is wound screw-wise a small plate of copper, the larger sides of which are covered with an incombustible dielectric, while the smaller sides are bare. The bare part faces the surface of soft iron, but does not touch it. Several sheets of iron, and several rows of copper plates, are thus arranged concentrically. Their length varies according to the diameter. The entire coil is 12c. in length, and ·03c. in diameter. The magnetism is acquired by a polar plate, where the real poles of the armature meet the real poles of the electro-magnet.

From the experiments made it results that the magnetic force of each sheet is sensibly the same, and that all combine magnetically. The sums of the real spirals, whose number is very limited, form a number of spirals with action four times as great; this is one reason why the resistance may be considerably reduced without changing the effect produced.

M. Germain having found, on the other hand, that the resistance of conductors is inversely proportional to their surface, and not to their volume, has given the conductor of the coil the geometrical form which offers the greatest surface with the smallest volume. A thin sheet fulfils these conditions; it is easy to obtain, to cover, and to wind.

All the soft irons communicating with the earth, and all the bare spirals being opposed, at a very small distance, then, when electricity of high tension comes into the bobbin, not only does it find only two ohms of resistance, in place of 500 to 1,000 in other systems, but it can turn to the earth throughout all its course.

The dielectric is incombustible, that it may not be deteriorated by the small sparks which might pass in the interior.

With such a system, atmospheric electricity comes into telegraph stations with about the sixth, at the least, of potential; it finds a conductor seventy-five times less resistant, and consequently seventy-five times less susceptible of being heated. The magnetic effects produced are the same.

Such, in short, is the ingenious invention of M. Germain. And it has not remained at the stage of theoretic conception. For nearly six months employed in the correspondence between the observatory of Puy de Dôme and the town of Clermont Ferrand, it has acquired the sanction of a long practice. M. Germain has received numerous orders. At present, when observations at high altitudes are multiplying, it is important to be able to communicate permanently with the region of storms. In devising his coils and applying them to the Morse apparatus, M. Germain has rendered a great service to science, and overcome the chances of danger which threaten telegraphists in such circumstances.

The Journal of the Franklin Institute. Vol. lxvi., No. 4.

Lightning and Lightning Rods.—A Letter from Mr. David Brooks.—My attention has been called to an article of Mr. Mott's on "Lightning and Lightning Rods," published in the August and September numbers of the journal, which contains many theories and notions at variance with those published by myself about a year since. Mr. Mott says: "Thus his Majesty's ship *Dictator* was struck and damaged by lightning at Martinique, in the year 1791, during fine weather and a clear sky." When effects are produced without cause miracles are wrought, and this is the latest recorded instance of a miracle. It is difficult to understand how any one who possesses any familiarity with the laws governing the propagation of the electric current, can believe that such an occurrence ever took place. "The return stroke often kills men and animals, or destroys buildings which are at the time at a great distance from the place where the direct discharge occurs." I have no hesitation in emphatically asserting that there is no such thing as a "return stroke" in an electrical discharge. There is a general inductive disturbance, or re-combination, whenever disruptive discharge takes place; but it is simultaneous with the discharge, and not an after result, and never "kills men and animals, or destroys buildings which are at the time a great distance from the place where the direct discharge occurs." In speaking of the effect and virtue of points over knobs or balls, my experiments show the very opposite of what he states to be true, and consequently I can neither appreciate nor subscribe to his remark or conclusion that, "Hence it (a point) may prevent a disruptive discharge which might otherwise occur." On the evening of the 4th of July, 1872, a thunder-storm passed over this city. Within the space of an hour over one hundred buildings were struck by lightning, or the effects of the lightning were noticed in over a hundred different places, leaving out many, probably a greater number, where the effect was unnoticed, or no damage produced. The discharges or flashes of lightning occurred as often as once per second during a portion of this hour. There were at least five thousand pointed rods in this city, and how much did they "produce an escaping current," or "prevent the accumulation of electricity," or neutralise the charged cloud?" Probably they did their level best, and prevented a discharge occurring oftener than once per second. The above example affords a practical illustration of the ability of points to silently discharge the accumulated electricity of the clouds, the earth, or the "return stroke," or the whole combined. Mr. Mott says "points are of vital importance before the instant of discharge arrives," and, he might add, of no account when they occur. "An improper termination of a lightning-rod is to connect it with the gas or water pipes of a city or village beneath the surface of the earth. Theoretically, it is the best possible termination; practically, one of the very worst," &c. Mr. Mott may connect a rod to earth in his way, and throw in any desired amount of charcoal. I will connect the same rod to a gas or water pipe, and then apply a current to the rod, and demonstrate that this current goes to the pipes in at least the proportion of a thousand to one. The author, further on, refers to Mr. Crosse's experiments, whereby he discharged fifty Leyden jars twenty times a minute, accompanied by reports "as loud as those of a cannon." This experiment was probably performed about the time the *Dictator* was struck, "during fine weather and a clear sky." I will only remark, in conclusion, that it would have been more satisfactory had the author adopted the phraseology of many parts of my paper without interpolations.

Tel Jour July 15, 76

A Victorian paper (B.C.) gives an account of some strange freaks of atmospheric electricity, during a recent thunderstorm. A lady residing next to a girl's schoolroom, heard a great crash in the building, and mentioned the fact to some friends. On entering it was found that the green baize doors near the entrance had been torn from their hinges, that the black boards lay on the floor, and that the lid of every desk, of which there were 144, was open and thrown back. Several of the lids had been torn from their hinges, others were partially so; but without exception every desk stood open, and some were half filled with water as if a bucketful had been dashed into them. The back door, like the green baize door, had been torn from its hinges and lay prostrate. The lightning evidently entered by the front windows, which were opened, and passed out of the back windows, which were also opened. Its course after leaving the building could not be traced. Had the accident happened two hours earlier, a dreadful tragedy might have occurred.

Elec News July 1. 75

Report of the "Commission on Lightning Conductors" Relative to a New Arrangement for Powder Magazines.—The new arrangement refers to the proposition of constructing air-shafts so as to place powder rooms in communication with the exterior air. The question asked by the War Administration of France was whether these air-shafts were sources of danger, irrespective of the lightning conductors erected around the magazines according to established usage. The answer given by the gentlemen forming this commission is:—"If the War Administrator adopts for his new powder magazines ventilation chimneys, and arranges the system of conductors so that the superior extremity of the chimnies remain always largely included in the generally admitted zone of protection, the commission is of opinion *the existence of these chimnies will not become in times of storms a special cause of danger.* However, in certain circumstances when, by reason of the impossibility of reaching an underlying inexhaustible sheet of water, or of the necessity of seeking for water at a large distance by conductors too much exposed to risk of malicious accidents, it is found advisable to give up supplying a magazine with lightning conductors, then air-shafts will be an element of considerable danger—especially when, on account of atmospheric causes, their interior sides becoming damp. Under such circumstances they should never be built."

Elec News Nov 15. 78

THE AURORA BOREALIS.—Prof. Edlund, of the Swedish Royal Academy, in a series of papers now being published in the *Phil Mag*, deduces the theorem that all other circumstances being equal, the resistance to the flow of the electric fluid from the atmosphere to the surface of the earth is greater at the equator and in the equatorial regions than at a certain distance from that circle, and that the resistance diminishes as the dip of the magnetic needle to the earth increases. And in this he discovers the cause not only of the strong disruptive discharges of violent tropic thunderstorms, but the rarer and gentler discharges of higher latitudes, culminating in the aurora borealis, in which the discharges are transformed into slow and continuous currents.

Proceedings of Societies.

THE SOCIETY OF TELEGRAPH ENGINEERS.

The Annual General Meeting of this Society was held at the Institution of Civil Engineers, 25, Great George-street, on the evening of Wednesday, the 13th ult. Mr. C. V. Walker, F.R.S., President, in the chair.

The adjourned discussion on Mr. Andrew Jamieson's paper "On a New Form of Lightning-Protector for Lines and Apparatus," was re-opened by the President, who remarked upon his form of Bobbin Lightning-Protector mentioned at the last meeting, and after having explained its construction, exhibited some which had been fused and otherwise damaged by lightning. The Acting-Secretary then read a communication from Mr. John Aylmer, the Honorary Secretary of the Society for France. Accompanying Mr. Aylmer's letter were two forms of Lightning-Protector employed by the French State Telegraphs, which he now presented to the Society. The first of these protectors was enclosed in a strong and water-tight cast-iron box, two sides of which were strongly glazed, to allow the interior to be readily inspected. In the interior of this box were two brass plates, each carrying 300 fine silvered points, which were opposed to each other, and separated by a uniform distance of about one millimetre. The lower plate was in electrical connection with the cast-iron box, which is itself when in use connected with earth. The upper plate was insulated by means of ebonite washers from the box, but had two insulated terminals connected to it passing through the top. To these are brought the line and instrument wires respectively. This form is intended to be employed outside the station.

The second protector consisted of three brass plates one above the other. The top plate carrying two hundred silvered points was insulated from the one below it, upon which its points projected, by ebonite washers. This in its turn was insulated from the lowest by a thin sheet of gutta-percha tissue. The first and third plates were in communication with each other by means of two brass clamps, which served to keep the whole together, and were connected to earth. The middle plate carried two terminals for the reception of the line and instrument wires. Thus the lightning either escaped to the plate below through the tissue, or above by means of the points. The whole was enclosed in a wooden box, and was intended for use within a station.

MR. LATIMER CLARK brought before the Society a form of Lightning-Guard of novel principle, a model of which was exhibited. It consisted of the usual two plates of iron or brass, separated by ebonite washers. The points, however, instead of being fixed, were movable in a vertical direction, through holes pierced through the upper plate for that purpose. The points were surmounted by a small knob or head, whose weight allowed the points to rest upon a thin piece of carbonised paper placed on the lower or earth plate. The advantage Mr. Latimer Clark claimed for this arrangement was that the points could be easily brought nearer to the earth plate, than they could by the use of ebonite washers alone, and that whatever number of points were used, they must all be separated from the earth-plate by a uniform distance.

MR. TREUENFELD remarked upon the principles and construction of Mr. Jamieson's form of protector, and expressed the opinion that whenever the station-clerk could not at a moment's notice examine the protector at the station if a fault occurred, or when tools were required to inspect the internal arrangements, uncertainty and dissatisfaction were sure to follow, and for that reason he preferred the old form of Siemens plate-protector.

MR. W. H. PREECE then entered upon the whole subject of Lightning-Protectors at considerable length. Starting with the assertion that our lines in England suffer more from atmospheric electricity than those of any other country, Mr. Preece gave several interesting statistics as to the damage done to telegraph plant and apparatus by lightning; and having explained the

Sir Robert Christison, Bart., recently read a paper before the members of the Botanical Society in Edinburgh, in which he described some observations he had made on an ash-tree near Dean Bank Toll, which was struck with lightning in 1874. This tree (one of a row) was about 30 feet from those nearest to it. It was for the most part exposed on the west side, and when, during the storm, it was struck by the lightning, this side suffered most from the electric fluid, which stripped off the bark and made two long narrow fissures in the trunk. In the spring of last year, but some fourteen days after the other ash-trees in the row had begun to bud, this one put on some buds. On the west side, however, where the electric fluid had taken most effect, not a single bud was visible. At the present time the great bulk of the foliage on the tree is very thin, and during the last three weeks it has made no progress. Sir Robert had spoken to the owners with regard to the purchase of the tree for botanical purposes, and found that they were favourable. He thought, however, before it was got, some further time should be given it in order that its further progress in the way of vegetation might be watched. At the conclusion of the paper, Mr. Potts called attention to a curious incident which occured two years ago at Lasswade Loan, when a flash of lightning ran along the telegraph wire, whose connecting poles were parallel to a row of ash and elm-trees, and the lightning, strange to say, passed the elm-trees and split the ash-trees. Sir Robert Christison said, in reference to Mr. Potts' remarks, that even in the days of Shakespeare there was a belief that some trees were more likely to be struck than others, and he believed the ash was one of these.

~~*On Crystals of Magnetic Oxide of Iron formed during the Roasting of a Spathic Ore.*—By M. Boussingault.~~

On a Remarkable Fall of Hail, observed at Gulta Ferrata. By P. SECCHI.

THE hailstones were formed of groups of crystals five or six sided, with pyramidal ends, round an irregular mass of ice. The groups weighed 40 to 60 grammes; certain blocks 300 grammes. The cloud was like a huge ball of cotton or wool moving from N.W. to S.E. It showed a whirling movement, and gave out a dull crackling noise, like that from collision of hard bodies. There were continuous and intense electric discharges in the heart of it. P. Secchi considers that in general electricity is not the cause, but the effect, of hail.

Automatic Discharger for Electro-Atmospheric Rods. By M. Serra Carpi.

This consists of a copper lever 30 centimetres long, with equal arms, turning about a pivot in communication with the part of the conductor which carries the discharge to the ground. At one end of it is a gilt ball, situated 5 centimetres from the end of the insulated conductor; the other end is fitted with a piece of soft iron. When the end of the lever has acquired sufficient tension to produce small sparks, attraction occurs between the gilt ball and the end of the insulated rod; so that the lever turning on its pivot, comes into contact with the rod. That this contact may be maintained, spite of wind and other disturbing causes, a small magnet is so placed, that when the first contact takes place between the lever and the rod of the conductor, a second occurs between the magnet and the other arm of the lever. The magnet should be so strong as to maintain the attraction by contact without attracting at a certain distance. This can be effected with an armature or a screw movement. The lever turns only in one direction, and it can be made immovable in case of a special observation. This apparatus has been tried at Rome during thunderstorms. Whenever the rod acquired a tension capable of producing sparks of two to three metres, it came automatically into communication with the ground, and the lever remained in contact with sufficient force for ordinary disturbing causes.

Elec. News July 8. 75

Electric Discharges on Fine Metallic Wires.—M. Melsens.—These studies are related to the question of lightning protectors by multiple conductors. In 1865 the author showed how the spark from batteries divides itself between all the metallic conductors in its path, in a similar manner to the spark from the great Ruhmkorff coil. In view of multiple conductors for lightning protectors, several experiments have been made with Holtz's splendid machine to confirm his old experiments; and he now states he has been able to lengthen the conductor of the smallest diameter, to introduce several thousands of Siemens's resistance units, and to still ascertain with the greatest facility that a portion of the current instantly passes through such a conductor. He also inserted long columns of ordinary water, distilled water, moist earth, dry sand, and various dry or wet gases, without essentially modifying the phenomena, on the express condition, however, that the two extremities of the conducting wires were put in contact with the two poles of the electric source; or were at least brought into very close proximity to them. "Ten years ago I proved," says M. Melsens, "that the spark from the great Ruhmkorff coil passes very easily through conductors of the same dimensions whether of copper or iron; but I then only experimented with conductors of very small length. Recently desiring to experiment with lengths as long as those of lightning conductors, I soldered into a brass sphere a copper wire 100 metres long, and an iron wire about 200 metres long—both being 0·1 millimetre in diameter. From this sphere the wire started, each separately, wound round long glass rods. The free ends were, in their turn, each soldered into a brass sphere. Now a spark striking the sphere into which the two wires are fixed, divides itself between them in such a fashion that if we place the two other spheres at equal distances from a conductor in contact with the opposite pole of the Holtz machine or Ruhmkorff's coil, the spark traversed the two conductors, or one of them if it offers a much smaller resistance." Measuring this resistance for a 2 Leclanché-element current it was found that the copper wire corresponded to 540 Siemens's units, and the iron wire to 3300 units.

The series of figures now presented illustrate amongst other matters the following actions :—

(1.) The attraction (or repulsion) of magnets by magnets.
(2.) The attraction (or repulsion) of currents by currents.
(3.) The attraction (or repulsion) of magnets by currents.
(4.) The rotation of magnets by currents.
(5.) The rotation of currents by magnets.
(6.) The rotation of a magnet round its own axis under the influence of a current.
(7.) The repulsion by a current of its own parts.
(8.) The mutual inductive action of solenoids and magnets, and of magnets and magnetic matter.
(9.) The flow of currents in conductors and conducting media.
(10.) The action on magnets of magnetic media.
(11.) The action of magnetic instruments, magnetometer, galvanometer, electro-dynamometer.
(12.) The action of magneto-electric machines.
(13.) The magnetic properties of cobalt and nickel.

The figure illustrative of the lines of force surrounding a current has been previously given by Faraday, Guthrie, and Barrett. Those illustrative of the attraction and repulsion of parallel currents, by Faraday, but imperfectly. Those illustrative of flow of currents in conductors by Kirchhoff, Guthrie, and Carey Foster and Lodge.

Those illustrating the action of the galvanometer and the Gramme machine were suggested to me respectively by Mr. C. W. Cooke, and Mons. A. Niaudet.

The photographs have been executed directly from the filing figures by Mr. Robt. Gillo, of Bridgwater, of the firm of F. York & Co., of Notting Hill, the eminent manufacturer of photographic transparencies for the lantern.

ON LIGHTNING CONDUCTORS AND ACCIDENTS BY LIGHTNING.

By RICHARD ANDERSON, F.C.S., Member of the Society of Telegraph Engineers.

Abstract of Paper read before Section A of the British Association, August, 1878.

At the present time at least one-half of all the public buildings, including the churches and chapels, of Great Britain and Ireland are without protection against lightning. As to private houses, it is safe to assert that not five out of every hundred have lightning conductors.

According to the reports of the Registrar-General, the number of deaths from lightning in England and Wales during the eight years from 1869 to 1876 reached a total of 182.

According to the report of Dr. Engel, Director of the Statistical Bureau of Berlin, the number of lives lost during the same period in Prussia was 819.

The terrible losses, both of property and human lives occasioned by lightning, are mainly due to three causes, namely: first, in not providing any lightning conductors at all; secondly, in not placing them in the right position, or in sufficient number to cover a given area; and, thirdly, in not having them regularly tested, so as to ascertain their constant efficiency. Even some of the first cathedrals of England, such as Peterborough, have no lightning conductors whatever, while others, supplied with them, Windsor Castle for example, are insufficiently protected, as is apparent to any competent observer.

If the entire absence of lightning conductors is the most prevailing cause of the still exceedingly great number of casualties occasioned by lightning, that of ill-placed or insufficient conductors is another deserving much attention. The mischief done in this case is not only that the conductor gives a false security, but that, should the dwelling on which it is placed be struck by lightning, it leads to the belief that the wonderful scientific discovery of Franklin is nugatory, or at least uncertain in its action. A case of the most instructive kind, in which a house with a proper conductor fixed on it was struck and damaged by lightning, came under my own observation quite recently; a heavy thunderstorm passed over it, and the electric discharge fell on one of the towers, knocking down part of a crenellated wall, not more than three yards from a lightning conductor, and then passing off without doing further damage. The conductor being new and in good order, it seemed at first sight a very extraordinary case; but the mystery of it was soon explained by an examination of the premises, which I undertook. I found that the roof of the tower on which the lightning fell was covered by a solid mass of lead, of unusual thickness, connected at one end with a large iron water-pipe about four inches in diameter. In this case the electric force, to get to this rival conductor, heavier in metal than the one designed for the purpose, and therefore offering the best road earthward, had to smite the brick wall in its way, and having done this, it went down the iron water-pipe into the ground, doing, as already mentioned, no more damage. Had the actual conductor either been larger, that is, heavier in metal than it actually was, or had it been connected with the mass of lead in the first instance, the lightning could never have struck the house. The incident forcibly illustrates the necessity of leaving the design and erection of lightning conductors to no others but those who have made a thorough study of the subject, since the work is not by any means so free from complexity as is commonly believed.

The third cause is the utter neglect of the conductor, when once it has been put in its place; other repairs to all sorts of public buildings are regularly executed, but the lightning conductor is taken no notice of and is never tested.

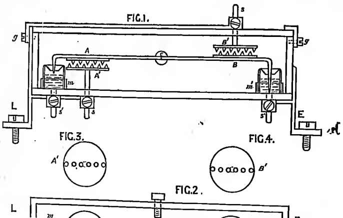
Having drawn attention to the chief causes of the numerous and fatal casualties caused every year by lightning, I have only to add a few words of advice as to how they might be prevented, or at least greatly diminished. First of all, I think it most desirable that public recommendation should be made, by local and other authorities, to place lightning conductors on all exposed or high-lying buildings, whether public or private, as well as on those standing near woods and on moist ground. It might be well worth the trifling expense to place simple conductors also against trees in parks, under which there are benches, or where persons are likely to gather during a thunderstorm, they forming a prolific source of fatal accidents. Above all, no church, chapel, school, prison, or other large public building, ought to be without one or more lightning conductors. But if it is necessary to greatly multiply lightning conductors, it is equally so that they should be planned, erected, and also periodically tested by competent persons, with scientific as well as practical knowledge of the work. The testing should take place at regular intervals, perhaps best in the spring, before the advent of the summerly thunderstorms, and it should likewise be made whenever a building has been undergoing repairs which may have damaged the conductor. To show the importance of constantly testing even the best laid conductors, I can cite another instructive case where a house was apparently well protected. On the 19th of August, 1876, shortly before midnight, a heavy stroke of lightning fell upon a mansion near Kew Bridge, Middlesex. The electric force destroyed the top of a large chimney, knocking off part of the coping, not more than two or three feet from a lightning conductor, to which it then flew, making its way down to the earth, but not without causing the greatest disturbance all along its path—lifting up, among others, some heavy marble toilet tables in bed-rooms some six feet distant on either

18

metallic disces oppositely electrified, the strength of that attraction determining the relative proximity of the discs.

Fig. 1 is a section, and fig. 2 a plan of the instrument (the cover and with it the plate B' has been removed in order to show the balance portion), while figs. 3 and 4 show the distribution of points on the discs A' and B'. A and B (figs. 1 and 2), are two copper discs, attached to the under and upper surfaces respectively of a stout copper rod, which being pivoted at *c*, *c*, forms a very delicate balance. The ends of the axis *c*, *c*, move freely in holes drilled in the ends of the screws, as shown in fig. 2. The discs at either end of the balance are provided while the whole of the balance, including the rod and discs A, B, are in permanent connection with the earth through the mercury in the cup *m'*, which is in metallic connection with terminal E.

The *modus operandi* is as follows:—So long as the line is free from the influence of atmospheric electricity, by virtue of B being slightly the heavier of the two arms, gravity operates, and draws it down till the prolongation at that end rests on the bottom of the mercury cup *m'*. If now the plates A', B', and the level of the mercury in the cup *m* have been properly adjusted, whenever the line becomes charged with atmospheric electricity, the discs A', B', being in metallic connection, become similarly



A NEW FORM OF LIGHTNING DISCHARGER.

By J. RYMER-JONES, late Electrician to the Imperial Government Telegraphs, Japan.

The principle involved in this instrument is somewhat analogous to that of the *attracted disc*, or *trap-door* electrometer of Sir William Thomson, inasmuch as it depends on the mutual attraction of

Commence over

by drawing B down, breaks the earth connection. The cups which contain the mercury are formed by small portions of test tubes, the rounded bottom being slightly softened by heat, and pressed inwards by a suitable point, so as to form a hole of the proper dimensions. This forms the top of the cup, which resembles somewhat the top of a *safety ink-bottle*. The bottom of the tube is open and is cemented into a brass cup, as shown in fig. 1. Not only does this form of cup circumscribe any possible splutterings of the mercury, but the level of the mercury is also seen through the glass, and, since the sides of the instrument case are of glass, adjustments may be made without removing the cover. When, however, this is necessary, in order to fill the cups and fix the balance, it is readily done by removing the screws *g g*, when the cover, together with the plate B', may be taken off.

Although such a modification will materially reduce the efficiency of the discharger, it is evident that by varying the connections, and putting A' to line and B' to earth, or *vice versâ*, the balance, when attracted, forms a bridge between the two. By employing the mercury cups, however, the contact with earth is not only more perfect, but there is less danger of the plates being fused together, as is not unfrequently the case with the ordinary *plate-dischargers*. Moreover, as the instrument is dust-tight and firmly screwed down, the mercury contacts, when once adjusted, need furnish no source of inconvenience.

EARTH CURRENTS.

By Chr. DRESING, of the Great Northern Telegraph Company.

Hoping to obtain some few additional facts to our present unsatisfactory knowledge of earth currents, I and Mr. Terp, the company's superintendent, a couple of years ago commenced a series of observations of earth currents on the Scotch-Norwegian Cable. The line being a busy one, was only occasionally (and especially on account of an interruption of the Norwegian and Scottish lines) at our disposal, and though the observations in consequence could not be carried out as frequently as could be desired, the following table, *which is a fair specimen of all the observations*, will be sufficient to demonstrate a certain regularity in the *diurnal variations* of the *strength* and *direction* of the natural current.

I may remark, that the deflections noted are readings from the scale of an *ordinary*, but sensitive *detector* of a resistance of about 1,200 ohms, and the strengths of the current and the deflections are not directly proportional to one another.

From this table and from all my numerous observations, which have tended to confirm the above results, without however, throwing any new light on the subject, the following conclusions may be derived:—

1st.—That there is always a natural current flowing through the cable.

2nd.—That this current is sometimes flowing from Scotland to Norway, sometimes in the opposite direction.

3rd.—That the current after each change of direction increases gradually, from a minimum to a certain maximum strength, and then again decreases until, after passing the zero-point, which only occupies about a minute, it assumes an opposite direction.

4th.—That the change of direction takes place about every six hours, *i.e.*, 4 times in the 24 hours.

5th.—That the *normal maximum strength* of the *natural current*—as proved by proper measurement—scarcely ever exceeds 3 to 4 Léclanché's cells.

6th.—That great *meteorological* disturbances *usually* are preceded, accompanied, or followed, by similar *electric* disturbances in the cable.

CONSTRUCTION OF LIGHTNING PROTECTORS.

By E. SAINT-EDME.

WHETHER the point of a lightning-conductor is made of platinum or of copper, or whether it is sharp-pointed, as suggested by Franklin, or presents an angle of 30° degrees, in accordance with the latest notions, however great may be the care taken in welding the metals, it is certain that in this respect the mode of construction is defective as regards conductivity, and it is to be feared that the conductivity is diminished by the action of the weather. But it appears further to be demonstrated that it is at the joint that a lightning protector is most often destroyed; it is there the discharge takes place.

At first, Franklin proposed that the conductor should be made of one metal only. It is owing to the rapid oxidization of iron that the successive Commissions have proposed to modify the nature of the extremity of the conductor. We think that it is possible to return to the original idea, since it is known how to cover iron with a metal (nickel) which forms on its surface a film perfectly protecting it from oxidization, and possessing the necessary conductivity.

We have experimented with the conductivity of nickel spread over a rod of iron. The nickelized surface indicated a rather higher conductivity than the mass of iron; it resisted better the electric discharges given off by a powerful battery. This same rod, after being immersed in water for 10 days, did not indicate any alteration, and the electric conductivity remained the same.

We think, then, that in the future construction of lightning protectors, it would be expedient to do away with the copper or platinum tips, the termination being made of a single piece of nickelized iron, the same as the conductor.

The lightning protector would thus become a safeguard against electric discharges, and, owing to the preservation of its point, would always possess the same protective effect.

Again, the conductivity would remain constant, and the necessity of supervision be done away with. This last condition is of great importance, as illustrated by General Morrin. According to him, it is desirable that you should be able to verify automatically the condition of the lightning protector as regards conductivity. In fact, everyone knows that if the conductivity is defective, the lightning protector becomes a source of danger.

Electrical News July 1 1875

Report of the "Commission on Lightning Conductors" Relative to a New Arrangement for Powder Magazines.—The new arrangement refers to the proposition of constructing air-shafts so as to place powder rooms in communication with the exterior air. The question asked by the War Administration of France was whether these air-shafts were sources of danger, irrespective of the lightning conductors erected around the magazines according to established usage. The answer given by the gentlemen forming this commission is:—"If the War Administrator adopts for his new powder magazines ventilation chimneys, and arranges the system of conductors so that the superior extremity of the chimnies remain always largely included in the generally admitted zone of protection, the commission is of opinion *the existence of these chimnies will not become in times of storms a special cause of danger*. However, in certain circumstances when, by reason of the impossibility of reaching an underlying inexhaustible sheet of water, or of the necessity of seeking for water at a large distance by conductors too much exposed to risk of malicious accidents, it is found advisable to give up supplying a magazine with lightning conductors, then air-shafts will be an element of considerable danger—especially when, on account of atmospheric causes, their interior sides becoming damp. Under such circumstances they should never be built."

Electrical News Sept 9 1875

No. 16, August 19, 1875.

Lightning Conductors.—The following are the results of investigations undertaken in France by a Commission to study the establishment of lightning conductors on the principal buildings of Paris. (1.) *Points.*—A stem consists of a conductor rising to a certain height above the buildings. The point should have a mass and conductivity sufficient to resist a disruptive discharge. Platinum points were found useless, and the Commission says—"Place at the top of each stem an 'arrow' of pure red copper, about 50 c.m. long, with sides sloping upwards 15° towards its central perpendicular." (2.) *Stems* should be of wrought iron, in one length, slightly conical. They should also be as much as possible galvanised, but under no pretext whatever should they be painted. The jointing between the stem and the conductor should be bolted, and well covered with a thick coating of tin solder. (3.) *Protecting zone of each stem.*—For an ordinary construction the stem efficiently protects *the volume of a cone* having the point for its summit, and the height of the stem—measured from the roof-ridge multiplied by 1·75—for radius of the base. Thus a stem of 8 metres protects a cone whose base, measured upon the ridging, = 14 metres radius, or 1·75×8. In practice the stems may be a little further apart, on condition that the "circuit of the roofs" be made use of. (4.) *Circuit of the roofs* means a metallic conductor making a circuit around the ridges of the roof. It must be in metallic connection with the lightning conductors of the building. (5.) Every metallic piece of considerable mass, forming part of the structure, should also communicate with the lightning rods. (6.) The extremity of the *rod* ought to be soldered to a metallic plate or hollow cylinder, of as large a surface as possible, and immersed deeply into water. *When it is not possible to reach a sheet of water the establishment of a lightning conductor must be discarded, as it would prove a source of danger rather than a protection.* (7.) The Commission recommends that conductors be completely inspected at least once a year, towards the end of autumn; moreover, their electrical resistance should be tested periodically by ordinary processes.

No. 17, August 26, 1875.

Electrical News Aug 26 1875

Construction of Lightning-Conductors for Electric Telegraphs.—M. Schaack.—The ordinary arrangements are objectionable on account of complexity (and consequent danger), uncertainty, expense, and the fact that when *e.g.* the opposed cones get fused together by the lightning, repairs cannot be done by the person who works the apparatus, &c. M. Schaack's arrangement is briefly as follows:—On the two long sides of a tin case (about 10 c.m. square section), at the top, are fixed two insulating wooden bars which carry binding screws C and C'. C is connected with the line; and from C' a wire passes through the telegraph apparatus and to the outside of the case, which is connected with earth. The screws are connected together by a loosely wound spiral of German silver wire, the silk covering of which has been passed several times through a caoutchouc solution. The case is filled three-fourths with water. When lightning enters the line, the spiral, with its thin coating, offers it a nearly direct path through the water to earth. The windings act like the points of a cone, &c., in other arrangements. The spiral is either fused, or its envelope burst through; and in both cases, the way to the apparatus is broken and the lightning passes more directly to earth. After the storms, the attendant fits a reserve spiral in place of the one destroyed. The length of the case depends on the number of line wires.—*Dingler's Polytechnisches Journal.*

21

Study of these tabulated results of involution will lead us to the principles by which we may write down the power of any binomial.

First, we perceive that the number of terms is always one greater than the power required.

Secondly, if both terms of the binomial are positive, all the quantities remain positive; but that a residual* binomial has its odd terms (counting from the left) positive, and its even terms negative.

Third. The exponent of the first or *leading* quantity (a) is always the index of the required power; and the powers of this quantity decrease by 1 in each successive term. The index of the second term of the quantity to be involved (b) (called the *following* quantity), begins with 1 in the second term and increases by 1 in each successive term until it equals the required power.

Fourth. The coefficient of the first and last terms is always 1. The coefficient of any term multiplied by the index of the first letter (leading quantity) in that term, and divided by the index of the second letter (following quantity) increased by 1 gives the coefficient of the next succeeding term. The coefficient of the second, and next to the last terms, is the index of the required power.

The algebraic formulation of the theorem is—

[illegible]

By the [illegible] A, B, C, for the [illegible]

[illegible]

the [illegible] becomes

[illegible]

[illegible] the foregoing rules, to raise $a+b$ to the sixth power. By the first principle, the number of terms will be 7. The signs will be plus.

The indices of the 7 terms will be a^6, a^5b, a^4b^2, a^3b^3, a^2b^4, ab^5, b^6.

The coefficients will be—

$$1,\ 6,\ \frac{6\times5}{2},\ \frac{15\times4}{3},\ \frac{20\times3}{4},\ 6,\ 1.$$

Collecting these steps, we have the complete expression—

$$a^6+6a^5b+15a^4b^2+20a^3b^3+15a^2b^4+6ab^5+b^6.$$

By substitution other binomials may be reduced to the form $(a+b)^n$. Thus, if the 6th power of $(3d+2e)$ were required, the result could be obtained by substituting a for $3d$ and b for $2e$. Then, raising $a+b$ to the 6th power, as given above, we afterwards obtain, by restoring the values of a and b, the expression—

$$729d^6+2916d^5e+4860d^4e^2+4320d^3e^3+2160d^2e^4+576de^5+64e^6.$$

Or it may occur that one of the terms of the binomial is a unit, as $(a+1)^n$. In this case, since every power of 1 is 1, and multiplication by 1 is unproductive of alteration in the product, the unit is usually omitted, except in its essential place, the first or last term.

For example—

$$(a+1)^3=a^3+3a^2+3a+1;$$

and—

$$(1+x)^n=1+nx+n.\frac{n-1}{2}x^2+, \&c.$$

By similar tact in dealing with problems, the binomial theorem may be made to include the involution of quantities of more than two terms. In the event, also, of one of the terms of a binomial being a fraction, as $(a+\frac{1}{2})^2$, tact affords a far better method than rule in solving the question. Thus, $a+\frac{1}{2}$ may be written $\frac{2a+1}{2}$, and

$$\left(\frac{2a+1}{2}\right)^2=\frac{4a^2+4a+1}{4}=a^2+a+\tfrac{1}{4}.$$

* A residual quantity expresses the difference of two quantities, as $a-b$.

LIGHTNING AND LIGHTNING-RODS.*

By JOHN M. MOTT

LIGHTNING is atmospheric electricity moving through bad conducting matter under an explosive form.

A lightning-rod is a conductor of electricity so applied to an object as to prevent the accumulation of free electricity upon it, by [illegible], and also to enable it to transmit, in safety, the electric force by which it may be assailed.

The construction and application of lighting rods has appeared to most persons a matter too simple to need aid from scientific minds, while not a few have looked upon the whole theory as absurd, and as a source of danger rather than of safety. There has been, consequently, but little encouragement for presenting to the public those facts which are requisite for guidance in applying the discovery of Franklin, successfully, to the protection of life and property.

The fact of electrical conduction by metallic substances having been long and well established, any further discussion of the application of this principle to the purpose of protection against injury by lightning may possibly appear, to persons conversant with such subjects, in some degree superfluous. The damage, however, which so frequently occurs in thunder-storms, attended, as it is, with loss of life and with serious inconveniences to the best interest of the country; the various theories advanced by persons who have only partially considered the facts; systems of rodding which have been adopted in different localities, and the numerous modifications of the conductors, each claiming some peculiar advantage over all its competitors, has created a curiosity, if not a necessity, which seems to call for investigation, and may be fairly offered as a sufficient reply to such an opinion.

When we consider the coincidences of lightning and ordinary electricity, together with the fact that atmospheric electricity may be conducted from the clouds, or strata of charged air, and applied to produce the same effects as those resulting from electricity generated by means of an electric machine, it becomes quite evident that the causes, whatever they may be, of ordinary electricity are identical with those of lightning; consequently we arrive at the important conclusion that lightning and common electricity are subject to the same

* Abstract of a paper read before the Meteorological Section of the Franklin Institute of Philadelphia. From the "Journal of the Franklin Institute."

Electrical News. Oct 14 1875

Description of a Special Lightning "Protector" for Aerial Lines.—J. F. Vaes.—A metal ring about 1 centimetres wide, and 2½ centimetres diameter, is cut in two; on one side the two ends are joined together by a hinge; on the other they are closed by means of a screw. This metal ring surrounds a hardened wooden reel, likewise divided in half, and perforated through its axis. The metal band is retained in position by the raised edges of the reel, and to its inner side a "preservative" point of aluminium bronze or platinum is fixed, which penetrates the reel to within 1 or 2 millimetres distance from the hole through it. In order to attach this "protector" to a telegraph wire, the metal band is opened, and with it the two halves of the reel. It is then placed upon the line wire, and closed by the screw so that the wire occupies the axial perforation. To the head of the screw is then fastened a gutta-percha-covered copper wire whose other extremity is affixed to a metallic plate in the post, or some other "earth." In this little device it is impossible for the "preservative" point to touch the wire; and it is, moreover, shut out from atmospheric influences. (1). The aperture of the reel should have its diameter a little smaller than that of the wire, in order that the "protector" be properly fixed. (2). To fill up the cleft that will always exist, more or less, between the two halves of the reel, place there some gutta-percha, or tarpaulin, before the reel is fastened: these materials, by compression, will entirely fill the cranny. (3). In times of thunderstorms the "protector" will give rise to derivations by reason of the small distance of the exterior surface of the band from the telegraph wire. Many means are available whereby this inconvenience may be remedied. It will be insufficient to varnish the metallic parts; it is much better to lengthen the reel, or to give greater height to the raised edges. Another means consists in covering the wire with an insulating layer for some centimetres on each side of the "protector;" but that which appears to be the most simple and efficacious is to as it were "house" the "protector," so as to protect it from the rain. (4). The construction, though based on the principles expounded, may be varied considerably, such as by replacing the single point with several points, or with a many-toothed metal plate, &c. (5). It may also be used without altering the supporting poles. One is not limited in the choice of situations, and one may thus regulate electrical discharges at convenient distances from cables and instruments, so that in case of a storm they would be found much less exposed to derivations.

Electrician Nov 11 1875

Double Maximum in the Frequency of Thunderstorms during the Summer Months.—M. von Bezold.—The results of this investigation are thus formulated:—Phenomena of thunderstorms show in general, during the summer months in the northern hemisphere, two maxima. These maxima approximate nearer to each other the further we go north. But not only can they be decisively proved for Germany, but they are distinctly recognisable (taking the principle of five-day sums) even in Barnaul and St. Petersburg. Among the places examined there is only one which showed but one maximum, and this is Katharinenburg, the climate of which is less influenced by the meteorological phenomena of the tropics than that of any other place taken into consideration. [In the tropics it has been shown that strictly there is summer twice in the year. These two maxima of temperature, which, as you remove from the tropics, approach each other very quickly, merging into one another in the high latitudes, appear much more strikingly in the frequency of the thunderstorms. Thus the phenomenon in question may be regarded as an echo of the two tropical summers, or heat maxima.]

AUGUST 15, 1874.

You again write to us without giving your name and address.

M. P. S. says: Your repeated cautions in regard to lightning rods lead me to ask your advice through your columns upon the following points: I have erected at my country residence a water tank and fixtures of rather novel construction. At one corner of the house, I have placed an old cylinder boiler, about 30 feet long and 3 feet diameter, standing on end, resting on brick foundation. The upper head has been removed, making a huge water tank. The top projects above the eaves of the roof, but not higher than the peak. It is encased in an ornamental frame tower connecting with the main building. I propose to keep this tank filled with water by force pump from the well. It is now empty, however. From this tower, iron water pipes lead to the kitchen and bedchambers, and also to the cast iron force pump in the well, and probably 20 feet down into the water. The house has two ordinary lightning rods on chimneys, leading to the ground on the opposite side of the house. 1. Is this arrangement dangerous? A. The arrangement as described is not to be called exactly dangerous, but might be made much better by a little change. 2. Would lightning be attracted by the large mass of iron of the boiler, rather than by the lightning rods, which are higher? A. If, as would appear, the iron tank is in excellent connection with the ground, it is quite possible that lightning might strike it or some of the pipes running from it to the house in preference to the lightning rods. 3. If struck, would the lightning follow the mass of iron to the ground, or pass through the pipes into the well, or enter the chambers through the discharge pipes? A. If the tank or its connections were struck, the lightning would, without doubt, go to the earth and not into the house. 4. Would it be advisable to put a lightning rod on the outside of the tower leading to the ground? A. A lightning rod on the tower should be put into perfect metallic connection with the tank, and need not extend below its upper edge. Let the tank and water pipes, in other words, be the lower part of the rod. 5. Would not this last tend to attract the lightning, and in such case would not the electricity be likely to leave the rod and enter the boiler with same effect as if no rod were there? A. Both your suppositions in this paragraph are correct. 6. Will not this large mass of iron resting on the ground and this indirect water connection answer the purpose of a conductor? A. This question is already answered in No. 2, assuming that the pipe into the well is in perfect metallic connection throughout, with no lead or cement joints. Red lead is an admirable insulator. In the way of advice we would say: Connect all your lightning rods together, and also to your iron tank and water, gas, or other pipes, not by separate connections, but so that there is some connection between all as high as possible. If you have a metal roof connect all rods with it. If not, connect them by a good sized conductor running along the ridge of the roof. Bear in mind that, to carry off the heaviest lightning flash known, a copper rod one inch in diameter is not considered too large, and, though of course such flashes are of very rare occurrence, they may come. Hence the great value of uniting your different rods high up. Read our article in vol. 29, p. 26, and our editorial remarks upon a letter, p. 111 of the same volume.

L'Électricité Aug. 76

entraîner aucun inconvénient sur son passage. Mais l'ingénieur dirigeant cette partie du service municipal a mis son *veto*. En conséquence, on est réduit à creuser partout des puits, quelquefois très-profonds, afin d'aller chercher fort avant la nappe conductrice.

N'est-il pas déplorable de voir que le défaut de compétence d'un seul personnage suffit pour entraîner des dépenses si considérables?

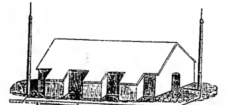
Nous ne savons comment il se fait que les membres de la commission se soient inclinés devant de pareilles prétentions.

***

On a fait à l'Académie des sciences des communications destinées à appeler son attention sur la mauvaise qualité que l'on puisse imaginer de l'ignorance dans laquelle on se trouvait alors en matière de paratonnerres. On avait armé de tiges innombrables un bâtiment qui était tout en fer, mais on ne s'était pas borné à cette étrange absurdité. On avait eu soin d'isoler avec de petits bouts de bois une couronne horizontale qui les réunissait tous, ainsi que les conducteurs destinés à mettre en rapport ladite couronne avec le réservoir commun.

Les paratonnerres en cuivre sont, de l'avis de tous les spécialistes, bien préférables aux paratonnerres en fer. Mais les ennemis du cuivre ont découvert un argument singulier.

Les voleurs qui dédaignent les paratonnerres de fer déroberaient les conducteurs de cuivre! Nous allons raconter une petite anecdote qui prouvera que les tiges de fer



A RUSTIC LIGHTNING ROD.—A French agricultural paper announces the discovery that bundles of straw bound on broom-handles and stuck upright over the roof will effectively protect a house from lightning. The first trials of this apparatus were recently made at Tarbes (Hautes Pyrénées) by some intelligent agriculturists, and the results were so satisfactory that soon afterwards eighteen communes of the Tarbes district decorated their houses with these "stuck-up" but at the same time unostentatious and ingenuous lightning protectors, and it is reported that there have been no accidents from lightning since. By what experimental process the intelligent agriculturists came to their conclusion is not stated; nor can we learn what the idea was which inspired the plan, although it appears to have been the old proverb about a hair of the dog which bit you, for it has long been known that witches ride the storm on broomsticks.

CHRONIQUE DES PARATONNERRES

La ville de Paris a pris toutes les précautions désirables pour que les paratonnerres de ses différents établissements publics soient construits d'une façon irréprochable. Mai les résultats sont loin d'avoir répondu au zèle des commissaires. En effet, on doit regretter que le budget municip ait été surchargé de dépenses inutiles à cause de l'entêtement d'un ingénieur.

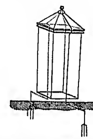


Diagramme montrant la disposition d'une cage dans laquelle un électroscope ne peut être influencé par une décharge extérieure.

La théorie des paratonnerres montre d'une façon tout à fait incontestable qu'il suffit que les tiges soient en commune action avec les tubes de la canalisation de l'eau pour que le fluide se rende dans le réservoir commun sans

No. 19. April 25, 1874.

Improved Lightning Rod.—Electricity is best dissipated by conductors which present a large number of sharp edges; and if such angles extend throughout the length of the conductor, the current is received at any point as readily as at the pointed apex. It is on this principle that Mr. Minsen, of Indianapolis, has invented his improved form of lightning-rod. In addition to these advantages, it presents a variety of others, rendering it, it is claimed, a thoroughly efficient protection to any edifice upon which it may be placed. The rod is composed of copper wires and large galvanized iron wires, manufactured into a single rope. The copper wires are square in section, and are drawn perfectly straight, so that when they are twisted up in the rod an innumerable number of sharp edges is presented. The iron wire is galvanised not only to prevent corrosion but to increase its conducting power. The presence of two dissimilar metals in the rod also results in constant magnetic action, whereby its effectiveness and durability is enhanced, while its electric condition is preserved. There are no joints in the invention to become disconnected and thus offer points of escape for the current. The rod is perfectly flexible, and can be bent to any angle or curve, while it cannot be broken from its fastening by the effect of wind or jars. Its continuity, therefore, is a point of considerable importance, which, taken in connection with the conducting capacity of the metals used, the spiral form, and the other advantages already alluded to, combines to render the device theoretically one of much value.

Lightning Conductors.—M. Colladon, the Geneva physicist, has published an essay on the subject of turning poplars into lightning conductors. He proposes to insert in the lower part of the tree a metallic rod in connection with the earth by a chain, so that the fluid cannot leave the tree to dart at any object placed within a short distance, which at present is very often the case.

[27107.]—Electricity from the Clouds.—The apparatus employed by Mr. Crosse consisted essentially of a series of poles projecting upwards into the air to a height of about 100ft. At the top of each pole was a sharp metal point, insulated from the support in an appropriate manner by means of an insulating stand or collar. These points were connected to one another, and to an insulated receiving ball in the observatory by means of about one mile of copper wire. This apparatus was erected at Broomfield, near Taunton, in Somersetshire. A somewhat similar arrangement was adopted by Mr. Ronalds, at the New Observatory, where observations were made for the British Association. The results of the combined observations of Messrs. Crosse and Ronalds are as follows:—1. The electricity of the air is always positive, increases after sunrise, diminishes towards noon, increases again towards night, after which it again increases. 2. The electrical state of the apparatus is disturbed by fogs, rain, hail, sleet, and snow. It is negative when these first approach, and then frequently changes to positive, with subsequent changes at every three or four minutes. 3. Clouds also, as they approach, disturb the apparatus in a similar way, and produce sparks from the insulated conductor in rapid succession, so that an explosive stream of electricity rushes to the receiving ball, which it is wise to let pass off to the earth. Similar powerful effects frequently attend a driving fog and heavy smart rain.—ELECTRICIAN.

On the "Gliding" of Electric Sparks.—M. Antolik.—This new phenomenon may be most easily obtained by coating a glass box with soot, and making an electric spark strike it. The "spark-streaks" (which mark the path of the spark) present two light parallel lines, and one dark line between them. The former evidently arise from a thrusting aside of the soot; the outer edges appear, in the microscope, somewhat thicker (they also show a number of dark and light triangles, evidently due to induction; the dark have their base, the light their apex, turned to the edge). In the middle black streak the soot seems compressed, and when water is poured on the rod the soot here remains, while it leaves the rest of the surface. And even when the last remnant has apparently been wiped off (with a cloth), the path of the spark may still be detected by breathing on the glass. The soot seems to have been pressed into the plate. Sometimes an inner white streak appears within the inner dark one. Some other appearances of similar nature are also

ARRANGEMENT OF LIGHTNING CONDUCTORS.—According to the views of Mr. Preece, presented at great length in a paper read by him before the Society of Telegraph Engineers, London, the two main conditions that determine a perfect lightning conductor are—that it shall expose, in some prominent position on a building, a metallic point, and that it shall offer from this point to the earth a path of little or no resistance to the passage of the current. He also asserts that, instead of the costly copper rods, the ordinary galvanized iron wire, known as number four, and which is one fourth of an inch in diameter, is amply sufficient for the purpose, in the case of any ordinary dwelling house.

The reason given by Mr. Preece for recommending telegraphic wire is based on the experience of English companies in protecting the poles of their telegraph lines. These, it appears, are invariably supplied with lightning conductors of number eight wire, running from the upper end of the pole to the ground, and it is stated that no pole so protected has ever been known to be damaged by lightning.

Among the precautions mentioned by Mr. Preece as necessary to be observed in fixing conductors, the first is that it should be solid and continuous, there should be no joint unless it be a well soldered one, and chain-like rods, braided rope, tubing, etc., should be avoided. The ground connection, too, must be sound and good, and each conductor, if there be more than one, should have a separate ground connection, but they should also be all connected together, and connected with the lead roofing and all masses of metal in their neighborhood.

L'ozone a été découvert par Schönbein en 1839, mais avant lui on avait déjà quelque idée de son existence et van Marum, Cavallo et Davy avaient déjà fait des observations à ce sujet. L'ozone trahit toujours sa présence dans l'air par une odeur particulière. C'est une transformation de l'oxygène sous l'influence de l'électricité et d'autres forces de la nature. Le phosphore s'oxydant lentement à l'air transforme l'oxygène en ozone. On suppose que l'oxygène est divisé par l'électricité en deux parties, l'une négative l'ozone, l'autre positive l'antozone. L'ozone agit comme matière oxydante plus énergiquement que l'oxygène. Dans l'air que nous respirons il y a toujours une quantité minime d'ozone $\left(\frac{1}{450000}\right)$. La quantité relative d'ozone dans l'air augmente avec la hauteur comme l'électricité. Pour les hommes et les animaux une petite quantité d'ozone a des effets rafraîchissants.

25

HEAVY LOSS FROM LIGHTNING ROD IGNORANCE.

On the 11th of September last the large woolen mill of Robert Fitton, Esq., at Cavendish, Vt., was struck by lightning and consumed, with a loss of $100,000; 130 persons were thrown out of employment. The mill was 45 feet wide, 106 feet long, 4 stories high. It had a flat, gravel-covered roof, and around the eaves ran a ⅜ inch iron lightning rod with vertical points every four feet. From the eaves rod six branch rods extended to the ground, five of which terminated at a depth of three feet below the surface, and the other was carried thirty feet underground to the bank of a pond. These particulars have been mostly furnished to us by the proprietor of the mill. The Boston *Commercial Bulletin* states that the insurance underwriters regarded the mill as particularly well protected against lightning, as there was upon it an unusual array of rods, which had been overhauled and put in good order during the year. Yet the mill was struck, the flames flashing instantaneously through the spinning room. The *Bulletin* thinks that the loss of this mill shows what value there is in lightning rods. The insurance companies had to pay $81,000 in settlement.

The principal comment we have to offer is that the burning of the Cavendish mill was a glaring example of the results of lightning rod ignorance. It would be difficult to find a more sagacious or enterprising body of business men than are the presidents, directors, secretaries, inspectors, and agents of our fire insurance companies. It would naturally be supposed that, in a matter which so directly affects their pecuniary interests as fire losses from lightning, they would take great pains to acquire knowledge concerning the means of safety, and promulgate the strictest requirements among insurers. But they appear to be lacking in this respect, although year after year the records of annual losses of millions in property, by fire caused by lightning, are forced upon their attention, and large sums of money in damages are drawn from their coffers. By consulting the naval records they may easily satisfy themselves that, while formerly the losses of ships and lives by lightning were enormous, the losses immediately ceased when rods were introduced upon vessels: and at the present day we seldom or never hear of a serious injury to or loss of life from lightning, upon a properly rodded ship. The same appliance that protects a wooden vessel at sea will protect a wooden building on land, and we will here briefly describe this appliance, though in doing so we only repeat what we have oftentimes published.

In general terms, a ship's lightning rod consists of a rope or rod of copper or iron wire, lashed to the rigging and extended from the sky pole down so as to connect at any suitable place with the copper bottom, which is in contact with the sea. The rod thus has for its terminal a very large surface of conducting material, larger in fact than the deck surface of the vessel, and the lightning passes off harmlessly.

The golden rule of safety for rodded buildings is analogous to the above. *The rod must have for its terminal a very large surface of conducting material*, placed underground in contact with the earth. Without such a terminal, no rod can be considered safe.

How large should be the conducting surface of the terminal, and of what materials made? The area of conducting surface necessary to ensure safety varies with the nature of the soil. If the ground is always moist, a smaller extent of conducting surface for the bottom of the rod will be safer than if the soil is generally dry.

To meet the contingency of a very dry soil at the driest season of the year, the electrician, Mr. David Brooks, of Philadelphia, recommends that the rod have for its terminal a conducting surface, placed underground, equal in area to that of the roof of the building; if this rule errs, it is probably on the side of safety.

Applying the Brooks rule to the Cavendish mill, the rods should have had for their terminals, underground, 4,770 square feet of conducting material, in contact with the earth, instead of which they only had the beggarly amount of less than thirteen square feet. No wonder that the building was struck.

Of what material should the terminals of lightning rods be composed? Iron or copper plates or pipes are the best material. In all cases where there are underground water pipes, the rods should connect with them. If these are of any considerable extent, nothing more is required. In cases where metal terminals cannot be provided, then good charcoal may be used in quantity sufficient to furnish the required extent of conducting surface. This substance ranks next to the metals in conductivity. It may be placed in a trench leading away from the building, with the rod extended along the center. Full particulars concerning lightning rods, the electrical laws concerning them, the electrician's tests for safety, and the best methods for their construction have been given, many times over, in our back numbers; but we propose to continue the subject from time to time so long as may be necessary. We are confident that, if the insurance companies were each to spend seven dollars and place the SCIENTIFIC AMERICAN and SCIENTIFIC AMERICAN SUPPLEMENT on file in their respective offices during the year 1876, they would derive many most valuable suggestions from our pages, not only concerning the means of safety from lightning, but the prevention of fires of every description: suggestions which, if required to be carried into practice by insurers, would save large sums of money to the companies.

Eng MISCELLANEA. Sept '75

THE commission appointed by the Prefect of the Seine to report upon lightning conductors, and the method of constructing them, recommend the use of copper terminal points instead of platinum.

LIGHTNING CONDUCTORS. 1876

AT one of the recent scientific conferences at South Kensington, Dr. H. J. Mann gave an account of lightning conductors, laying particular stress upon the necessity of providing a sufficient outflow for the lightning channel. He gave the arithmetical proportions which must be observed between the height of the conductor, its circumference, and the outflow; and mentioned that coke saturated with water was the best material in which to imbed the base of the conductor for the purpose of establishing sufficient earth contact. It is not necessary, he said, in answer to a question, to insulate the conductor if the proper proportions are observed. He described Sir William Snow Harris's model which is exhibited in the collection, and showed how that distinguished man, by connecting the conductors fitted to the masts with the copper sheathing of ships, established sufficient contact with the salt sea-water. Water itself, he remarked, is not an effective receptacle for electricity, but every impurity in water greatly increases its use for the purpose.

26

PROTECTION FROM LIGHTNING.

During a recent thunderstorm in the village of Trumbull, Conn., a family of three persons, husband, wife and child, who had taken refuge on a feather bed, were instantly killed by lightning; the house had no rods. In the same village, during the same storm, a dwelling house, which had two lightning rods upon it, was seriously damaged. Several of our readers, who have seen the accounts of these disasters, and others who cite analogous examples, have had their faith in feather beds, as a place of safety during thunder storms, severely shaken; while some of them would fain believe that lightning rods serve to destroy rather than to preserve life and property. We are asked to print something upon the subject; and we cheerfully comply, promising, however, that there is little that is new to be said, and that the subjoined information has for the most part been heretofore reiterated in our columns.

ARE FEATHER BEDS A PROTECTION FROM LIGHTNING?

Feather beds are not a protection from lightning, and the popular belief that they are, doubtless results from a misapprehension of the laws that govern the passage of electricity. The human body is a better conductor of electricity than feather beds or other objects ordinarily contained in the apartments of dwellings, and therefore, *a priori*, when the lightning enters an apartment, the human body is likely to form one in a chain of inductions, determining the path of an electrical discharge, unless better conductors are in its vicinity to divert this action.

WHAT IS THE SAFEST PLACE DURING A THUNDERSTORM?

The only place of absolute security in a thunderstorm is an iron building; or next in safety is a building properly protected by lightning rods.

Houses constructed entirely of iron manifestly stand in no need of lightning rods at all, because the electric fluid, on striking so good a conductor, would rapidly diffuse itself in all directions and flow into the ground, provided, of course, that the construction of the building is such as to allow its free escape.

ARE LIGHTNING RODS OF ANY REAL VALUE?

Unquestionably they are. Examples are numberless where the lightning has been seen to fall upon the rods of buildings and descend harmlessly to the earth; while the fact is undisputed that the principal damages suffered from lightning are in connection with buildings that are not provided with conductors. Notwithstanding these facts, some people are apt to be indifferent whether their houses and stores are provided with lightning rods or not, and are always ready to give an example where some building so provided was struck in spite of its protection. Such cases are quoted by the old fashioned "practical man" with much satisfaction, because they hail in them what they are pleased to call the victory of their sound common sense and the discomfiture of the scientific men. This class is, however, rapidly diminishing in numbers under the influence of the extensive diffusion of scientific education among the people.

It may be well to assure unbelievers that the efficacy of the lightning rod is no longer an open question, and that any

SEPTEMBER 5, 1874.] Scien Amer

failures are attributable *to bungling or ignorant construction.* It would be an easy matter to multiply statistics in proof of the assertion; but none would carry with them more force than the following statement obtained from the records of the British navy, by Sir Snow Harris, F. R. S.:

"Between 1810 and 1825, before rods were introduced, no less than thirty-five sail of the line and thirty five frigates and smaller vessels were completely disabled; and in 200 cases recorded, 306 seamen were either killed or injured. When the lightning rod was introduced, every mast was furnished with a capacious conductor permanently fixed and connected with bands of copper passing through the sides of the ship under the deck beams, and with large bolts leading through the keel and kenson, and including, by other connections, all the principal metallic masses employed in the construction of the hull" (Harris). Since the adoption of this arrangement, "it appears that damage by lightning has positively vanished from the records of the navy."

In England, the various telegraph companies suffered serious damages by every thunderstorm, by the destruction by lightning of their poles. The poles are now provided with small lightning rods, and all damage has ceased.

In this country the Western Union Telegraph Company has suffered in the same manner, especially, says a recent number of the *Journal of the Telegraph*, "upon the plains and prairies, where every lightning storm formerly shattered and destroyed more or less of our poles, but which are now fully protected by a conductor (No. 8 wire) placed on every fifth pole. Wherever telegraph poles are provided with such lightning rods, all damage is prevented. Where the poles are not provided with rods, damage ensues.

WHAT IS THE PROPER SIZE AND MATERIAL FOR HOUSE LIGHTNING RODS?

According to the best authorities, a copper rod of one inch in diameter, or an equal quantity of copper under any other form, will resist the effect of any discharge of lightning hitherto experienced. The copper rod is therefore the safest and best material that can be used, but it is expensive. Iron rods of one inch in diameter are very commonly used, and, if pointed with solid copper and properly put up, are efficacious in the great majority of cases. The particular form of the rod makes no difference. It may be round or square, twisted or hollow, composed of one solid piece or made of wires twisted together. It is the quantity of metal contained in the cross section of the rod that is of value, not the form.

WHY SHOULD THE ROD BE POINTED?

The reason for terminating lightning rods in a point is as follows: When a thunder cloud highly charged with positive electricity comes up, it repels the positive electricity of all bodies on the surface of the earth coming within its influence, and causes negative electricity to accumulate in them. This is called induction, and it always takes place before a discharge. Now it has been discovered that, when electricity is accumulated in a body in this manner, it can most readily escape by sharp points because in them it meets with the least resistance. A lighted candle held near the prime conductor of an electrical machine furnished with a point will be nearly blown out by the current of air produced by the escape of the electricity. Lightning rods are therefore provided with sharp points to allow the accumulated negative fluid to pass off readily into the air and neutralize the positive fluid of the thunder cloud.

HOW SHOULD RODS BE MADE AND APPLIED?

The object being to make so good a passage for the lightning to the ground as to remove all danger of its leaping to some conductor in the house, the greatest care must be taken not to have any break in the conductivity. As it is inconvenient to manufacture or transport the rods in one piece, the different parts must be in intimate connection when they are put up; it is best to have them soldered and the joints protected from the air and moisture.

The point of the rod should be extended a little above the chimney or highest part of the building, and should be fastened in contact with the building by staples or cleats. Glass insulators should not be employed. It makes no difference in conductivity whether the rod is painted or not painted.

No building can be said to be properly rodded or protected against lightning, unless the lower part of the rod or terminal under the ground is made quite extensive. The extremity of the rod should connect with masses of good conducting materials, such as old iron, or iron ore, or coke, or charcoal, laid in trenches, or the rod itself should be elongated, sunk deep in the ground, and carried a considerable distance from the building, and put in connection with water or moist earth if possible. The golden rule for safety is: "Provide the largest possible area of conducting surface for the terminal of the rod."

Scientific American. Oct 23, 1875

Origin of Atmospheric Electricity.

According to M. Bécquerel, solar spots, which are sometimes 10,000 leagues in extent, appear to be cavities by which hydrogen and various substances escape from the sun's photosphere. But hydrogen, which appears here to be only the result of decomposition, takes with it positive electricity, which spreads into planetary space even to the earth's atmosphere and to the earth itself, always diminishing in intensity because of the bad conducting power of the successive denser layers of air and of the crust of the earth. That would then only be negative, as being less positive than the air. The diffusion of electricity through planetary space would be limited by the diffusion of matter, since it cannot spread in a vacuum.

That gaseous matter extends further through space than the distance which is generally assigned to the earth's atmosphere will be proved by the fact that auroras, which are due to electric discharges, are produced at hights of 100,000 and 200,000 yards, where some gaseous matter must exist.

M. De la Rive agrees with M. Bécquerel as to the electrical origin of the aurora, but considers that the earth is charged with negative electricity, and is the source of the positive atmospheric electricity, the atmosphere becoming charged by the aqueous vapor rising in tropical seas. The action of the sun, he considers, is an indirect action which varies with the state of the sun's surface, as shown by the coincidence in the periods of aurora and sun spots.

In the accounts of travelers in Norway, we often read of their being enveloped in the aurora, and perceiving a strong smell of sulphur, which must be attributed to the presence of ozone. M. Paul Rollier, the aeronaut, who descended on a mountain in Norway 4,128 feet high, saw brilliant rays of aurora across a thin mist which glowed with a remarkable light. To his astonishment an incomprehensible muttering caught his ear; when this ceased he perceived a very strong smell of sulphur, almost suffocating him.—*Manual of the Natural History, Geology, and Physics of Greenland.*

LIGHTNING CONDUCTORS.—At a recent meeting of the *Académie des Sciences*, M. Saint-Edmé gave some interesting information on lightning conductors. If not thorough conductors throughout their whole length, they are far worse than useless, for, in such a case, they attract the lightning and then allow it to escape by a channel which offers less resistance, to the great danger of the edifice; it is, therefore, necessary that the condition of these appliances should be inspected at certain intervals. The author, while endeavouring to find a suitable method of ascertaining automatically any loss of conducting power, has introduced a great improvement into the manufacture of lightning conductors themselves. This consists in making the iron rod in one length, and by electro deposit, giving it a thick coating of nickel, which is an excellent conductor of electricity.

Eng. Dec 75

27

(25) E. G. A. says: I am continually seeing statements to the effect that, during a thunderstorm, the electricity passed down the lightning rod, escaping into the ground. Is not the reverse the case? Does not the electricity pass from the earth up the rod and neutralize the electricity of the cloud overhead? If not, why not put a ball on the upper end of the rod and point the lower, for has not experiment demonstrated that electricity will flow off a point with more rapidity than off a round surface, and the reverse in passing on? If this be not the case, what is the necessity of placing balls on the posts of an electrical machine and points on the ends of the spokes of an electrical wheel? A. It is conventionally assumed that the current always passes from positively to negatively electrified bodies, so that what we call its direction depends altogether upon which is the positive and which the negative body. As a matter of fact, the atmosphere is usually positive relatively to the earth; but it is evident that the action of the clouds upon each other, under the influence of different currents of air, may result in charging them with opposite electricities. When the conditions are favorable, they then act inductively on the earth, the positive cloud inducing a negative charge in the portion directly under its influence, and the negative cloud a positive charge. If a rod is present or the degree of electrification is sufficiently great, a discharge takes place from the earth to the cloud in one case, and *vice versa* in the other. It is not correct, therefore, to say that the discharge is always in the same direction when referring to any one rod. Points receive and give off charges more readily than surfaces do. It is in consequence of this fact that round surfaces are used with the electrical machine, and points with lightning rods, the object being an accumulation of electricity in one case and its dissipation in the other.

The Electrical Condition of Air in the Arctic Regions.

Scien. Amer 11 Nov 1875

M. Vikjander, during one of the recent Swedish expeditions to the arctic regions, made extended investigations into the electrical condition of the air there existing. All of his observations agree in showing that the atmosphere conducts electricity at temperatures relatively high, a circumstance to which may be attributed the absence of thunder and the presence of the aurora borealis. It has been suggested that this is due to the great humidity of the air in such regions; but it is evident that the phenomenon must be ascribed to other causes, since the same temperature and the same degree of humidity do not produce a like effect in lower latitudes. At less temperatures, —4° and —13° Fah., and below, the air isolates better.

Generally the arctic atmosphere appears to be positively electrified, and the earth negatively. In several instances, the air was effectively electric of itself, and this not due to terrestrial induction. During certain periods of the spring, at a time when the air isolated relatively well, both ground and air were charged with negative electricity. This change of electrical state of the atmosphere was not a constant consequence of greater cold; but when the temperature had been lowered for some time, the air had an evident tendency toward a negative condition.

There seems to be a natural connection between these facts and the aurora. During the months of January and February, the latter phenomenon appeared daily, and was especially noticeable on the 10th and 26th days of the latter month. It then disappeared, to reappear, however, on the 2d of March.

At the same time, changes in the electricity of the air were observed, suggesting the theory that the negative electricity, deprived of the possibility of discharging itself into the aurora, was obliged to accumulate in the lower atmospheric strata, which isolated relatively well. From the 2d to the 11th of March, the aurora returned; and during this period the air was in a good conducting condition, or else, when effecting isolation, was positively charged. Subsequent to the latter date, the auroras ceased entirely, and an interval supervened, of low temperature with negatively electrified air, which lasted until the increasing light of the season of the year precluded further auroral observations.

28 Scientific Amer.

LOOK TO YOUR TERMINALS.

A lightning rod which is not properly connected with the earth is quite dangerous. The very common method of merely sticking the lower end of the rod down into the dry earth near the surface of the ground is bad, and endangers the building, because dry earth is such a poor conductor, and the amount of rod surface in contact with the earth is so small. Under such conditions, a portion of the electric current will be likely to find an easier path to the earth, through the building than through the rod; and a part of the electricity will therefore leave the rod, strike into the building, and down, in various directions into the earth, making havoc as it goes. As a measure of prudence, house owners should *look to the terminals* of their lightning rods, and place there a considerable amount of the conducting materials above named.

By adopting this simple expedient, many buildings, otherwise unsafe, will be rendered comparatively secure from damage by lightning.

As an electrical conductor, well burnt charcoal ranks next to the metals. Metallic ores come next to charcoal. Water and moist earth, which are so frequently recommended as terminals for lightning rods, are among the poorest of conductors.

One of the best protected buildings that we have heard of is that of Mr. John Knox Smith, an intelligent English merchant residing at Singapore. His country house is built on a promontory, upon a bed of iron ore, with which the house lightning rods are made to communicate. The lower ends of the rods thus have a very extensive conducting surface, and the protection afforded is considered perfect. Thunder storms and lightning strokes are very frequent, but the house has never been injured.

PROTECTIVE AREA OF RODS.

It was supposed to have been established by Charles and Gay Lussac that a lightning rod protected an area whose radius was double the hight of the rod extending above the building, but this rule is no longer reliable by reason of the extensive use of metals in the shape of pipes, etc., in the construction of the buildings of our day.

WATER AND GAS PIPES SHOULD BE CONNECTED WITH THE LIGHTNING ROD.

When electricity finds several paths to the ground, it will prefer the best, it is true; but some portion will also pass along the poorer conductors. If, therefore, any metallic substances lie within the area supposed to be protected, they are in danger of being struck. This is especially true where the lightning has a chance to jump to the gas and water pipes of a building. It is a good plan to connect these pipes with the lightning rod; if the rod is struck, the electricity will then have an excellent path into the ground and will be rapidly diffused over the vast underground network of pipes. The danger to the inmates of the house of being struck from these pipes is less than that of receiving a shock from the powerful induced currents, liable to be developed in them, if unconnected, during a thunderstorm.

IS MORE THAN ONE ROD USEFUL?

The more rods on a building the better, especially if all are connected with each other near their upper ends.

Multiple lightning conductors are useful because each one helps the others, and if the discharge is too great for one, they will be able to carry it between them, but what is more important is this: The less the total resistance of the conductor to earth, the more certain is it that no other, undesirable line will offer an approximately good path to the earth, and so get a part of the flash. Thus, suppose a single rod whose resistance is 1, and that a series of bolts, hinges, gutters, stove pipes, etc., offers another line (passing perhaps through the walls of the house or the body of its occupant) whose resistance is 3. Now, under these conditions, a flash would be likely to divide itself, and while ¾ would go safely down the rod, ¼ passing along the other line might burn the house or kill the men. But if two rods were connected, the resistance in this line would be but half, hence ⅚ would take this road and but ⅙ tend to go by the other. Again, the less the resistance of any line, the higher the opposite charge developed in it by induction, and hence the greater its attractive influence, leading the discharge to prefer it as a path. This bears upon the importance of connecting all accidental lines of conductors, such as gas and water pipes, with the lightning rods. Insulated, these are opposition lines, soliciting the lightning to come into house and traverse them; connected, they help the rod as we have seen to get and keep the lightning outside.

METAL ROOFS, GUTTERS, LEADERS, AND WATER TANKS SHOULD BE CONNECTED WITH THE LIGHTNING RODS.

Finally, in the way of general advice, we would say: Connect all your lightning rods together, and also to your iron tank, and water, gas, or other pipes, not by separate connections, but so that there is some connection between all, which connection should be as *high up as possible*. If you have a metal roof, connect all rods with it. If the roof is not of metal, then connect your rods together by means of a good sized conductor *running along the ridge of the roof*. Bear in mind that, to carry off the heaviest lightning flash known, a copper rod one inch in diameter is not considered too large; and though of course such flashes are of very rare occurrence, they may come. Hence the great value of uniting your different rods high up.

E. M. Nov '76

BEADED LIGHTNING.

M. G. PLANTE, whose experiments in reference to globular lightning have recently attracted attention, describes an uncommon kind of this meteor that he observed during the storm at Paris and its environs on the 18th August, 1876, about 6 a.m. It is not yet properly classed in meteorology, and is calculated to throw a new light on the globular thunderbolt. The flashes that darted from the clouds that obscured the sky were of great length and varied form, as bifurcated, in curves with multiplied points, and with closed contours. It appeared generally composed of brilliant points like ridges of fire, produced on a moist surface by an electric current of high tension.

Some of the most remarkable passed from the cloud to the ground in the form of an elongated S, lasting for an appreciable instant, like a string of brilliant grains distributed along a narrow luminous string. Observed from the heights of Meudon, this lightning appeared to strike Paris in the direction of Vaugirard, where it fell.

This formation of luminous beads alternating with streaks of fire—a consequence of the electric fluid passing through a ponderable medium—is altogether analogous to a string of incandescent globules presented by a long metallic wire melted by a voltaic current, the extremities of which remain suspended an instant in a state of fusion at the poles of a pile or to the swellings and knots resulting from the flowing of every liquid vein. Such agglomerations of electrised and luminous matter should naturally dissipate themselves more slowly than the bolt that develops them, which explains their persistence in this case.

This kind of lightning shows the transition from the ordinary sinuous or rectilinear lines to the globular form. It may be conceived, in fact, that if the electric condensation upon some points of the lightning is more considerable, the beads may acquire a certain volume, and give birth to globules remaining some time visible.

M. de Moncel records a similar phenomenon during a storm in London on the night of the 19-20th June, 1857, when several flashes persisted for some instants, and only disappeared after being, as it were, melted into granular light. M. Planté considers we may unite these examples of lightning under a particular character, and classify them as "beaded lightning" ("éclairs en chapelet.")

M. Trecul also observed some curious effects during the same storm, whilst occupied writing between 7 and 8 o'clock before an open window. At the time of the nearest flashes small luminous columns descended obliquely on his paper. The length of one of them was about 2 metres, and the breadth of the largest ½ decimetre (0·15m.) One more particularly under notice, the one obtuse at the furthest extremity, became attenuated gradually, and was only from 3 to 4 centimetres while at the surface of the table. Their appearance was that of inflamed gas with badly defined contours; their colour, of little intensity, was yellow, slightly reddish, like that of many flames; but at the surface of the paper where they were agitated for 4 or 5 seconds the tints were more lively. M. Trecul does not well remember the lower part of the first, but the second presented the lively colours (yellow, green, and blue) of the rainbow: the third was of a very beautiful blue of weak tone, almost white at the contact with the paper. No detonation took place, but there was a feeble rustling when the fluid was just about leaving the paper, a noise something like that when a little water is spilt on a metal plate sufficiently heated. No odour was exhaled: the paper was neither altered nor spotted, the steel pen was not struck (*atteinte*), and M. Trecul felt nothing.

Lightning Rods.

The committee appointed by the Prefect of the Seine to superintend the construction of lightning conductors in Paris has been changed into a permanent one. A sum of $10,000 has been appropriated by the municipal council for reconstructing all the lightning conductors in Paris, or at least all those which may be found defective or inefficient. This sum is a first instalment, as the whole of the work, it is supposed, will cost $250,000, although the committee do not recommend the use of copper conductors.

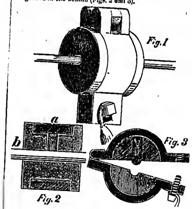
Until the appointment of the committee, lightning conductors were constructed by ordinary blacksmiths, under the superintendence of architects who knew nothing of physics. A competitive adjudication took place recently, between a number of competent electricians, for the construction of all the lightning conductors on the Paris municipal monuments. The successful competitor is M. Groot, the well known electrician. A list of instructions with seventy carefully drawn provisions has been published. The continuity must be tested yearly, and the contractor will be paid by instalments; so that his claim will be cleared up only when the efficiency of his work shall have been tested during a certain number of years. The platinum cone has been abolished and replaced by a copper cone. The quality of the iron, as well as of the copper and solder, is to be tested by chemical analysis. The insulation of rods has been abolished as being useless. The committee has diminished the diameter of protection area, which was supposed to be twice the hight, and has reduced it to 1·45. The consequence is that rods are to be multiplied.—*Nature.*

29

TELEGRAPH LIGHTNING PROTECTOR.

By J. E. Vaes.

A RING of metal (Fig. 1) about 1½ centimetres wide, and 2½ centimetres in diameter, is cut in two. On one side the two halves are held together by means of a hinge, and on the other side they shut by means of a screw. This ring encircles a bobbin of hard wood, also cut in halves, and bored through its axis. The raised edges of this bobbin prevent the metal ring slipping off. In the interior of the ring is fixed a protecting point of aluminium, bronze, or platinum, which extends within a distance of one or two millimetres of the groove in the bobbin (Figs. 2 and 3).



To apply the protector to a telegraph wire, the ring, and with it the two halves of the bobbin (Fig. 3), are opened and placed on a wire of the same gauge as the groove in the wood. The ring and the bobbin are then closed with the screw, care being taken to pass under the head of the screw a copper wire covered with gutta percha, the other extremity of which is connected with a plate of metal attached to the bottom of the post, and making a good earth connection.

The lightning protector following all the vibrations of the wire, it is impossible that there can be a contact between the wire and the protecting point, and the point itself is excluded from atmospheric influences.

REMARKS.

1. The diameter of the groove in the bobbin should be slightly smaller than that of the wire to which it is intended to be fixed.

2. To fill up the chinks that will always exist to a greater or less extent between the two halves of the bobbin, it is sufficient to introduce, before fixing to the wire, a thin layer of gutta percha or tarred cloth. These substances, giving way to the pressure, fill up the chink entirely.

3. In case of rain, the lightning protector might give rise to derived circuits, owing to the short distance between the exterior of the metallic ring *a*, and the wire *b* (Fig. 2). Several methods suggest themselves to remedy this defect. It would be insufficient to apply a coat of varnish to the metallic parts; it would therefore be better to lengthen the bobbin so as to increase its length on either side of the ring, or even to heighten the edges of the bobbin.

Another method consists in covering the wire with an insulating material for a distance of some centimetres on each side of the protector. That which appears the simplest, and at the same time the most effective plan, is to surround the lightning protector with a covering, thus removing it from the influences of rain. Owing to its small dimensions (the protector can easily be covered with the hand), the application of this last suggestion would not be difficult.

4. It is unnecessary to say that whilst retaining all the principles on which the construction of the protector is based, it can be varied in different ways—as for instance, by replacing the protecting point by several points, or by a small plate of metal provided with teeth, etc.

5. This protector can be applied without making any special alterations to the posts. One is not limited in choice of position, and the lightning can thus be given the possibility of expending itself at a convenient distance from instruments and cables, which will find themselves in case of storms much less exposed to derived circuits.—*The Telegraphic Journal.*

July 1876

(80) M. A. G. says: We desire to put a lightning rod upon a church spire, 120 feet high. About 12 feet of the top is a galvanized iron finial, which terminates in a point covered with gold leaf. Would you advise us to carry the rod above the finial, or would it be better attached to it, so that the finial will constitute a part of the rod? If the latter is the best plan, how would you attach the rod to the galvanized iron? Would it be well to simply put the rod around one of the waists of the finial? A. The rod should be attached to the base of the finial by a firmly soldered and riveted joint, so as practically to make an unbroken connection. All joints in the rod should be firmly soldered and secured against separation. If the soil is dry, you will need a large amount of conducting material placed underground in connection with the rod. See p. 400, vol. 33.

Peculiar Effects of Lightning on Vines

At a recent meeting of the *Société Helvétique des Sciences Naturelles*, Professor Dufour mentioned a lightning stroke which in the month of June last, struck simultaneously two vineyards, distant over 360 feet apart. In one, the surface affected measured 57 feet square, and included some 330 vines. In the other the surface was about 32 feet square and about 100 vines appeared to be destroyed, while others were partially so. In August, however, those vines which appeared to be the most severely injured threw out vigorous branches, and early in September were covered with new bunches of young grapes. But on the other hand, those grapes already started, and which, had the lightning not intervened, would have formed the year's crop, ceased all development.

In his treatise on lightning, Arago cites, as remarkable facts of rare occurrence, lightning strokes apparently divided into two or three branches. Here, however, the lightning divided into two branches to strike vineyards considerably distant from each other, and then the branches must have produced 330 and 100 jets respectively in order to strike the separate vines.

Lightning Conductors.—Messrs. R. S. Newall and Co., of the Strand, London, the well-known lightning-conductor manufacturers, have, we understand, entered into a contract to supply their copper-rope lightning conductors to the South African International Exhibition buildings which are to be opened at Cape Town on the 15th of March next.

Dec 76

Construction of Lightning Protectors.

"Whether the point of a lightning conductor is made of platinum or of copper, or whether it is sharp-pointed, as suggested by Franklin, or presents an angle of 86° in accordance with the latest notions, however great may be the care taken in welding the metals, it is certain that in this respect the mode of construction is defective as regards conductivity, and it is to be feared that the conductivity is diminished by the action of the weather. But it appears further to be demonstrated that it is at the joint that a lightning protector is most often destroyed; it is there the discharge takes place.

"At first, Franklin proposed that the conductor should be made of one metal only. It is owing to the rapid oxidization of iron that the successive commissions have proposed to modify the nature of the extremity of the conductor. We think that it is possible to return to the original idea, since it is known how to cover iron with a metal (nickel) which forms on its surface a film perfectly protecting it from oxidation, and possessing the necessary conductivity.

"We have experimented with the conductivity of nickel spread over a rod of iron. The nickelled surface indicated a rather higher conductivity than the mass of iron; it resisted better the electric discharges given off by a powerful battery. This same rod, after being immersed in water for 10 days, did not indicate any alteration, and the electric conductivity remained the same.

"We think, then, that, in the future construction of lightning protectors, it would be expedient to do away with the copper or platinum tips, the termination being made of a single piece of nickelized iron, in the same way as the conducting rod is made.

"The lightning protector would thus become a safeguard against electric discharges, and, owing to the preservation of its point, would always possess the same protective effect.

"Again, the conductivity would remain constant, and the necessity of supervision be done away with. This last condition is of great importance, as illustrated by General Morin. According to him, it is desirable that you should be able to verify automatically the condition of the lightning protector as regards conductivity. In fact, every one knows that, if the conductivity is defective, the lightning protector becomes a source of danger."—*E. Saint-Edmé.*

Lightning.

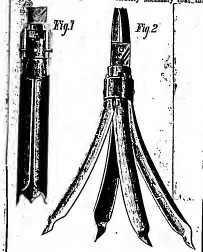
The celebrated experiment of Benjamin Franklin, by which he demonstrated the identity of lightning and the common electric spark, was performed by him in June, 1752, at Philadelphia, Pa. Having made a small cross-stick kite, he covered it with a silk handkerchief instead of paper, so that it would stand rain, attached a tail, etc. The upper end of the cross had an iron point, connected by a string to the usual kite cord, which was of hemp. To the lower end of the cord an iron key was attached, and to that a short length of silk ribbon, as a non-conductor, by which the kite string could be safely held in the hand. On the approach of a thunderstorm he proceeded to a common near the city, and, with the assistance of his son, sent up the kite. Ere long the thunder cloud approached, the electricity came down the kite string, and Franklin, standing under a shed, received the electric sparks through his knuckles which he applied to the key, and charged his Leyden jar by putting its conductor in contact with the key. The rain then fell, which improved the conductivity of the kite cord, and the electricity appeared in increased quantity.

76

The news of this wonderful experiment rapidly spread over the world, and was extensively repeated. In France, Professor Romas made a kite seven feet high, with a fine wire interwoven in the string. The kite was raised five hundred and fifty feet, and is alleged to have yielded flashes of electric fire ten feet in length. In St. Petersburgh, Professor Richman, while attempting to repeat Franklin's experiment, received so heavy a charge of electricity that he fell dead. This was in 1793.

WESTON'S LIGHTNING ROD DISCHARGING POINT.

In order to render lightning rods of any efficacy as a protection to a building, it is absolutely necessary that the



Scientific American.

ground terminals shall be large, and sufficiently so to discharge all the electricity from the rod. The object of the device illustrated herewith is to secure an extensive metallic surface in contact with the earth, with comparatively little cost and trouble.

The device consists of four metallic arms, formed as shown and riveted about a central socket. When closed, the point appears as in Fig. 1. To attach it to the lower end of the ground rod, the pivot of the latter is inserted in the socket and the nut screwed on from the inside, as represented in the broken away portion in Fig. 1. A hole is then made in the earth with a crowbar, and the point, with the section of rod attached, inserted. When at the bottom, by forcing the rod down, the sheets or arms of the point will spread out as in Fig. 2, thus giving a large discharge area. The nut which connects the lower section of the rod with the point is left loose, so that the former is allowed to turn when screwing it into the section above. To attach the point to cables, a zinc ring is first put on, then the discharger, and then another ring near the end of the rod. The discharger and upper ring are slipped back to their proper position and fastened with set screws.

Patented through the Scientific American Patent Agency, March 7, 1876. For further information address the inventor, Mr. J. H. Weston, 29 West Sixth street, Cincinnati, Ohio.

Lightning.

The celebrated experiment of Benjamin Franklin, by which he demonstrated the identity of lightning and the common electric spark, was performed by him in June, 1752, at Philadelphia, Pa. Having made a small cross-stick kite, he covered it with a silk handkerchief instead of paper, so that it would stand rain, attached a tail, etc. The upper end of the cross had an iron point, connected by a string to the usual kite cord, which was of hemp. To the lower end of the cord an iron key was attached, and to that a short length of silk ribbon, as a non-conductor, by which the kite string could be safely held in the hand. On the approach of a thunderstorm he proceeded to a common near the city, and, with the assistance of his son, sent up the kite. Ere long the thunder cloud approached, the electricity came down the kite string, and Franklin, standing under a shed, received the electric sparks through his knuckles which he applied to the key, and charged his Leyden jar by putting its conductor in contact with the key. The rain then fell, which improved the conductivity of the kite cord, and the electricity appeared in increased quantity.

The news of this wonderful experiment rapidly spread over the world, and was extensively repeated. In France, Professor Romas made a kite seven feet high, with a fine wire interwoven in the string. The kite was raised five hundred and fifty feet, and is alleged to have yielded flashes of electric fire ten feet in length. In St. Petersburgh, Professor Richman, while attempting to repeat Franklin's experiment, received so heavy a charge of electricity that he fell dead. This was in 1798.

LIGHTNING RODS,

which may be described as follows:

a has a series of points formed of spiral coils, combined with a tubular portion, forming the tip. The conductor is a flat strip. *b* is a jointed tubular conductor for vessels. It is divided at the head of the lower mast, a branch leading down the shrouds on either side to the water. *c* is an iron rod tipped with copper, the point of which is gilded. *d* has a central copper slip inclosed between iron side pieces; the points of connection have interposed zinc plates. At *e* the iron rod is grooved to receive a copper slip. The joints are secured by screw-threaded washers. At *f* the point is formed with two opposite wings. The rod, *g*, is composed of a single strip of copper wound spirally so as to form a tube. *h* is composed of several strands of wire laid together so as to form a rope, and having several tips. The point, *i*, is formed of three or more metals inclosed one within the other, the most fusible outside. *j* is an insulating attachment with additional conductor points at the coupling of rod sections. *k* is a copper cable, composed of a central wire rope and two exterior strands laid up in opposite directions. *l* comprises two or more copper wire ropes intertwined with an equal number of iron rods. *m* is a series of metallic strips, forming a tube, are joined together. *n* is a metallic strip, doubled up or corrugated so as to form a tube with spiral flanges. At *o* the joints of the rod are coupled by pieces cross shaped in section and secured by rivets and bolts. *p* has four twisted rods with wire warming. At *q* the tubular sections are united by short pieces, slotted inside so as to form a species of bayonet joint, and held by pins. *r* is composed of two strips of sheet metal, riveted together at their angles and twisted spirally. The strips in *s* have slots through which staples fasten them. *t* is connected by short pieces fastened by pins, *u* is an exterior cable stiffened by a spirally flanged core, and the sections of *v* are secured by plugs fastened by indenting the tubes into suitable depressions. At *w* the sections are coupled by an interior cylinder and a tapering plug projecting from each of its ends. At *x* an interior tube with

Fig. 6.

32

An inquest has been held on the body of William Stevens, killed by a telegraph wire at Islington. It appears that the wire broke before the accident, and that a gentleman, with the best intentions, made fast the end to some railings, but left it hanging across the omnibus yard, and that the poor deceased drove at a trot against the wire. The evidence given on behalf of the post office is stated to be to the effect that "the wire in question would have been taken down next year because of its being worn out. It would have lasted till then but for the violence of the storm." This does not seem very satisfactory. If all the other wires over head are run to within a year's estimate of their life, every heavy gale must bring some down, even if their life can be estimated to a year by the most competent judges. Apr 76

EFFECT OF LIGHTNING ON TREES.

A Swiss savant named Colladon has made some interesting observations in regard to the effect produced on different kinds of trees by lightning. In the neighborhood of Geneva Lake, where these observations were made, the poplar tree suffers least from lightning, seeming to conduct it away rapidly. Oaks, when struck, lose the tops. Elms are as little injured as poplars. Colladon has found that *young* pear trees recover from the effects of lightning, but old ones die, which seems to be a proof that young trees are better conductors. The practical conclusion that he draws from this is that poplar trees may serve for lightning rods when planted near houses, provided care be taken to connect the lower part of the trunk with a well or moist ground by means of a strong metal plate buried in the earth. Without this precaution the electric current may leave the tree and take another direction. This happened in one case, where it took an oblique course through a house in order to reach a neighboring puddle. If the ground water is not very deep, this is not necessary, as on river banks and in valleys.

FREAKS OF LIGHTNING IN ITALY.

Correspondence of the London Echo. 77

Rome, July 12.—Padre Secchi publishes an account of the singular phenomenon which occurred at Velletri during the violent thunder-storm of June 28, and which is to be ranked among the hitherto unexplained caprices of nature. Just as the tempest was at its hight, and the rain torrential, six persons taking shelter in a stable, which was also occupied by three horses harnessed to as many wine-carts, witnessed the extraordinary appearance. A luminous mass rose from the threshold of the door, entered the stable, glided from one cart to another, attracted, probably, by those fringes of bells characteristic of the Roman wine-carts, and then passed through an iron grating into the street. The bells rang, the horses plunged, a woman and a man felt a certain giddiness of head; but no accident happened. Outside the stable, a carpenter at his shop-door saw the luminous mass (which some of the witnesses compared to a fiery club as thick as a man's arm) issue from the grating, the pavement, and disappear in a dazzling flash. However, the meteor visited several portions of the large house with which the stable was connected, flew through large chambers, blackening slightly a gilt cornice in one, and scattering fragments of plaster in another. Strangest of all, this extraordinary visitor, after completely destroying the new ceiling of a room leading into a vast kitchen, danced round a woman who was standing at a table. She described the meteor as a fiery serpent, which she first saw standing upright on the floor, within two metres' distance of her. Then it flew toward her whirling several times around her knees with great velocity. She felt a sudden blow on the head and fell to the ground; but her husband, who saw the whole apparition, on rushing to what he supposed was the corpse of his lightning-destroyed wife, found that she was only stunned a little. On recovering, she complained of pain in the scalp, and her hair had become and remains, dry and rigid. After this last caprice the meteor disappeared, and from the quantity of soot which fell from the chimney, it is supposed to have found vent in that direction. It was accompanied by a loud detonation, but whether on its first appearance, or when it vanished, none can say. These details are gathered from a letter written to Padre Secchi from the Meteorological Observatory at Velletri, and published in the *Voce della Verita* of July 9. After this one may believe that Tanaquil really did see a "lambent flame" play around the head of Servius Tullus in his cradle; nor can the tale of the stars playing on the River Moldau at Prague over the body of St. Jean Nepomuc be so certainly set down as a pious fancy of the Middle Ages, unsupported by natural phenomena.

[28010.]—Lightning Conductor.—I would not use gas-piping unless fully lto. Better by far to use copper rod or rope made of a thickish wire. The ends are better tipped with some non-oxidisable metal; this will make the conductor last longer. The great point in lightning conductors is not so much the top as the bottom. I would run the rod down into the earth, and connect it with a large plate of iron or copper placed in some damp spot, into which occasionally the rain might run, so as to keep a good connection between earth and rod.—W. J. Lancaster.

STRUCK DEAD BY LIGHTNING.

From the Sioux City (Iowa) Journal. 77

While the thunder storm of yesterday afternoon was raging at a distance of apparently a couple of miles from this place, a singular freak of nature took place in the striking by lightning of the depot, and the striking and killing subsequently of J. H. Boyer, the postmaster and blacksmith of this place. At about 5 o'clock in the afternoon, at which time not a cloud obscured the sky overhead or stood between the sun and the town, a terrible flash of lightning, followed by a deafening peal of thunder, struck the wires of the telegraph office and set it on fire. The damage done to the telegraphic apparatus was most complete, the wires being torn to pieces and the different instruments being almost without exception distorted and broken and completely wrecked. Immediately after the stroke John H. Boyer, who was in his shop at the time, ran out in the street toward the depot, where some boys had been playing. He approached them rapidly and said, "Why, boys, I thought some of you had been struck. I was frightened on account of you." He evidently had it in his mind that the terrible shock might have frightened his family, as he started toward his home immediately. When within about fifty yards of the house, from the front window of which his wife was anxiously watching his approach, another vivid flash of lightning dazzled the eyes of all, and ere the thunder had ceased rolling the naked body of the unfortunate man was seen to be lying prone upon the ground. A number of people, among them his wife, rushed to the spot, and so horrible was the situation that it was not until he had been carried to the house that a full appreciation was had of the terrible death which nature had inflicted upon him. An examination of the body, from which every vestige of clothing, not excluding even a pair of cowhide boots, had been instantly torn, showed that the subtle and terribly fatal fluid had first struck him on the top of his head, whence, though the skull was left apparently intact, the hair had been burned off for the space of the size of a silver dollar. Thence the fluid had run down the side of his face, as was shown by a clearly cut track, to the shoulder, and thence to the heart, where it apparently had spread all over the body.

The terrible power of the fluid was shown by the presence in the ground, on the spot where the unfortunate man's body had been picked up, of a hole eight feet deep by actual measurement. The clothing of the deceased was found to have been shredded and when first discovered was on fire, while the silver watch he carried had been driven into the ground, and when lifted up, it was found that the works had been fused into a lump of shapeless metal.

33

BALL LIGHTNING.—A very fine display of this interesting meteor was witnessed at Vence, in the south-east of France, on the night of March 21-22, by M. Ed. Blanc, of which an interesting detailed account has just appeared in the *Comptes Rendus* of the French Academy, p. 666. Toward midnight there was observed, about eleven miles north-east of Vence, a large black thundery cloud, in a state of extreme agitation, and continually raising and lowering its position. At the upper part of this cloud three or four balls of fire issued every two minutes, as if from the invisible centre of the cloud, diverging in all directions, and after running a course of from six to eight degrees, broke silently with effulgent brightness. Their apparent diameter, as seen at a distance of eleven miles, was about a degree. They were mostly of a reddish colour, a few, however, being of a yellowish tinge, but all of them assumed a white colour in the act of bursting. Their course, which was horizontal and parallel to the plane of the cloud, was relatively slow, not exceeding two degrees per second, and they bore a strong resemblance to immense soap-bubbles, both as regards apparent lightness and general appearance. From time to time a discharge of lightning passed through the cloud from above downwards, followed some seconds after by a dull rumbling sound. The cloud, with its fine display of fire-balls, took a course from east to west, passing about a league to the north of Vence. The glimmering of the lightning with its low dull thunderous sound continued for more than an hour, after which the sky became darker and darker; rain mixed with hailstones fell, and lightning, accompanied with thunder, furrowed the sky in all directions. 77

A new electromagnetic lighting instrument has recently been described in *Dingler's Polytechnisches Journal*, by M. Hess. It consists of a chromic-acid element, a small induction coil, and a vessel containing a mixture of alcohol and sulphuric ether. The pressure of a knob puts the zinc of the element in contact with the liquid, and the small induction sparks inflame instantaneously the vapours of ether liberated from a sponge, which has been dipped in the mixture of alcohol and ether. According to the inventor this instrument has the advantage of lasting a long time without requiring any attention. 77

ASCENDING LIGHTNING.

[14887.]—May not "J. T. M.'s" experiment (letter 14738, p. 601) be an illusion itself? If the electric spark be limited to the apparent time a flash of lightning is seen by the eye, he might see (perhaps impossible) the spark begin and end its career.

Now, suppose lightning to be visible for the space of, say, one minute, an observer would see it travel downwards or upwards, as the case may be, at the beginning of the flash; but soon after would be unable to say which way the fluid was travelling. It would seem to proceed from that part of the flash his eyes were directed to; but as the beginning of a flash is followed almost instantly by its disappearance, an observer would be able to say whether it rose upward or downward. I therefore think "F.R.A.S." really saw an upward flash.

G. W. B.

SCIENTIFIC

The Causes of Atmospheric Electricity.—In continuation of an article under this head, on page 58 of our volume for 1876, we will now give some additional detailed explanations of the Northern lights by M. Luthstrom, as published in the *Archives de Geneva.*

The phenomena of very extensive northern lights extending over a large space, are usually produced as before explained; but the same phenomena can be produced in another way. Let us imagine that a cloud, charged by induction from the earth with +E below, and −E above, be driven by the wind from the southern countries toward the Polar regions; it may happen that the +E of the lower part of the cloud is discharged slowly into the earth without luminous effects, while the +E of the space of rarefied air combines with the −E in the upper part of the cloud with the production of light. This was repeatedly observed during the Swedish Polar expedition of 1868; it happened that the upper borders of the clouds were luminous, and this form of the phenomenon developed itself especially in a brilliant manner during a tempest on the ocean near Van Buren Island.

It is evident that the nature of the surface of the earth in those countries where the aurora borealis takes place has a great influence on the phenomena. If the surface is equal and level, the passage of the current will be made more easy. A surface covered with snow and ice must be very unfavorable to the electric currents, but it contributes to augment the tension before the neutralization commences, and it is for this reason therefore that the northern lights mostly appear in winter. They are nevertheless often seen at the end of the summer or at the beginning of the autumn.

A singular case was observed during the expedition in Lapland, in 1871–72; the aurora showed one single ray, which raised itself above Mount Suussavaara, where, for the abduction of electricity, an apparatus had been erected, composed of fine points of copper, put in communication with the earth. Though it is not certain, it seems very probable that the ray was caused by the presence of the apparatus in that locality.

The measures which have been taken to determine the hight of the Polar auroras above the earth, have only given approximate results, which are still sufficient to determine that it is truly above the layer of air in which the conducting power is at its maximum. Usually the lower border of the bow of the aurora borealis has been fixed at about 60 miles above the surface of the earth, that is to say, more than double the hight of the best conducting layer of atmospheric air which we have considered. It has been found that this hight varies greatly. The Polar aurora in the northern countries can even become as low as the region of the clouds. The experiments made with the Geissler tubes prove that a luminous effect can be made at a pressure of 1¼ inches mercurial column, and if the air contains enough moisture, at 5 to 6 inches, if the electric charge is only strong enough. This is not the case with the earth, for its electric tension is very small, but its great surface fully compensates for this. Experiments with different spheres have shown that a greater sphere with the same charge illuminated a Geissler tube at a distance at which, with a smaller sphere, there was no more effect. The hight of the aurora borealis is, in any case, small compared with the radius of the earth; but even if the distance of the aurora borealis from the earth was to be brought to 60 to 80 miles, that would not affect our theory, for though the conducting power be at its maximum at a pressure of three 16ths of an inch, it does not prove that a luminous phenomenon must show itself more readily at that pressure. This depends upon the heat developed by the current which illuminates the molecules of the gas; and this can be done by a much weaker current when the gas is rarefied, for then the quantity of heat needed is much smaller.

The great distance of the arc of the rays of the aurora from the earth shows thus that atmospheric conductibility extends to a considerable distance towards the higher regions. The phenomenon begins usually in the lower conducting layers of the rarefied atmosphere, (the regular way is to begin with an arc which extends itself upward by rays of undulating light.) It is therefore the lower parts of the conducting air layer which play the principal *rôle.* The currents which pass the upper layers are undoubtedly caused by the equilibrium being destroyed by the currents which go to the earth from the lower layers. These layers seem to neutralize themselves soon enough, to judge by the short duration of the rays of the aurora compared with those of the arc itself, which proves besides that they have only a secondary importance, the principal phenomenon remaining—the electric current of the atmospheric conductor through the intermediate layer toward the earth.

We will also say a few words concerning the double periodicity of the aurora borealis—the one of 10 years, the other of 60 years, which seems well established through the labors of Weld, Loomis, and others. The theory which we have advanced is the result of the hypothesis that the aurora is a phenomenon belonging entirely to our globe, and is produced by forces which have their seat in the earth itself. The system of the two conductors, the earth and the rarefied air, does not exclude the possibility of a direct electric influence from the sun and the planets, which has been looked upon as the cause of the periodical variation; but the supposition of such a direct influence becomes only necessary when meteorology proves that such a periodicity does not exist in the phenomena which have their cause in the heat of the sun, as, for instance, the cyclones and the tempests; when, on the contrary, that periodicity is proved, it would in that case prove a relation with other phenomena, as the quantity of evaporation on the surface of the earth and the periods of the aurora should be considered as a consequence of the periodicity of said meteorological phenomena, a periodicity the cause of which should be looked for only in the changes of the sun, indicated by the corresponding periods of the spots on that body.

The solution of this latter question seems important in regard to the study of the electric phenomena on the earth and in the atmosphere, because the possibility of discovering the correct laws governing these phenomena will then be greater.

Lightning Rods—How the Centennial Buildings were Protected.

…the Editor of the Scientific American:

Your recent articles upon lightning rods supply much-…eded information relative to the most important requisites …r protection. The following system, as applied to the Cen…nial Machinery Hall, combines great economy with the …st perfect protection and security, and may frequently be …opted with advantage for large buildings.

The tin roof of Machinery Hall has an area of 14¼ acres, … this is utilized as a lightning conductor in this manner: …ing above the roof are 100 wood terminals (used as flag …es), to each of which is attached a copper wire rope ⅜ inch …diameter, its upper end rising a few inches above the top … pole; at its lower end the wires are spread out, and 3 … of its length is firmly soldered to the tin roof. Earth …ons from this massive roof conductor are made at ten …erent places by soldering one end of copper ropes to the tin …f, the other end being firmly attached to 8 inch city water …s in the ground. Thus it will be seen that every square … of this huge building is covered and thoroughly pro…by an ample conductor; and it is believed there is no …g in this country so perfectly protected as this. The …st was only one tenth the amount requisite to protect …e usual way with rods, or less than $50 per acre.

…a connections being all-important in all cases, I would …mend the following for country buildings: Extend the …g rod underground, say 20 or more feet from the …; fasten and solder to its end a sheet of copper 2 by … dig a pit 3 by 6 feet, and 4 to 6 feet deep; put 2 … in depth of finely broken charcoal over the bottom, …t in the plate and rod, with another layer of charcoal …w inches of earth; then fill up to surface with loose …stones, leaving it so that the rainfall can freely find …y down to the copper plate; water from the roof may … into the pit. One such earth termination is of more …an half a dozen of the usual kind.

…delphia, Pa. J. D. Rice.

Lecture Representation of the Aurora Borealis

I have recently employed a simple device for giving to an audience a vivid idea of an aurora, and that has been to paint a representation of it with Balmain's luminous paint. When dry the drawing may be hung up in the lecture-hall and covered with black tissue-paper until required. At the appointed time the lights are lowered, the tissue-paper withdrawn, and magnesium wire burnt in front of the painting. I had last week the pleasure of showing this to an audience of 500 persons, and from the expressions of curiosity and approval found it to be a very taking experiment. Wm. Ackroyd

Sowerby Bridge, March 10

SOME EARLY EXPERIMENTS WITH LIGHTNING.

SIGAUD DE LA FOND compared him who should attempt to capture the lightning and to use it for electrical experiments to the ancient hero who, cuirassed in triple brass, was the first to trust his life to the hazard of the waves. Benjamin Franklin proposed the risk. In a letter written in 1750 he says, "In order to decide whether thunder clouds are or are not electrified, I propose to construct on the summit of some lofty tower or steeple a kind of sentry box (see Fig. 1, for which with the other engravings here given we are indebted to *La Nature*) large enough to contain one

Fig. 1.

man and an insulating stool, and to keep both well sheltered and dry. If from the middle of the stove there starts a bar of iron, curved toward the door, then carried vertically upward for twenty or thirty feet and terminating in a sharp point; by means of this conducting rod the man standing on the stove may be electrified by the low flying storm clouds. If there be any danger to fear for the man, although I am persuaded that there is none, he must step off the stool, stand on the floor of the sentry box, and every now and then bring near the bar a hook of brass wire which leads up to the metal covering of the roof. With this apparatus, if the rod becomes electrified, the sparks will pass from rod to wire without touching the man."

D'Alibard, an amateur in physics, had the boldness to carry Franklin's suggestion into execution. At Marly-la-Ville, he says, in a memoir read before the French Academy of Sciences in 1752, in a meadow on elevated ground he erected an iron rod about an inch in diameter and forty feet in length, having a steel point. A triangle of three posts, thirty feet or so in height, was erected, two posts being attached to a garden wall and the third standing alone. All three were strongly braced by beams and cordage. Against the wall the sentry box was arranged, the insulating stool being merely a piece of plank supported by four wine bottles. The arrangement is exhibited in Fig. 2, which is a fac-simile of a wood-

palms in their fore-arms, searched for the cause and found bright red stripes on the flesh, just as if a few small lashes had been administered. There is no doubt but that the villagers saw no good in these supernatural manifestations, and when they all perceived about the persons of the priest and his companion a marked sulphurous odor, due of course to the ozone generated, they were confirmed in their ideas that the powers of the nether world had been evoked.

The remarkable experiment above detailed (we add a sketch of the scene from an old print) resulted in others being undertaken. Delor of the University erected a pole 99 feet high and obtained the sparks; others followed, and investigators into the phenomenon began in the laboratories of all the scientists. But these wise gentlemen did not play with the lightning unscathed. Scarcely was there one that could not show its marks on his person. A soldier, employed by Abbé Chappe to turn his electrical machine, underwent the same experience which Professor Tyndall has so graphically described: the reception of a heavy charge of static electricity, which knocked him heels over head among the apparatus, smashing the same, and leaving the victim insensible for an hour. Finally, the terrible death of Richmann, of St. Petersburg, occurred, and for a time the physicists suspended

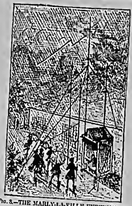

Fig. 3.—THE MARLY-LA-VILLE EXPERIMENT.

their dangerous experiments. Richmann was struck by ball lightning, a variety which M. Gaston Planté has only very recently explained (see SUPPLEMENT, No. 61), and which possesses an explosive power comparable to that of the most potent torpedoes, yet greater. The unfortunate man was standing near a rod which he had carried up through the roof of his house, and was in the act of presenting to it an electric gnomon in order to measure the degree of electrification of the passing clouds. The gnomon was simply a metal rod entering a glass vase at the bottom of which copper filings had been placed, though for what purpose it is

cut of the period. The iron rod was attached to the posts by silk cords, and its lower end bent twice so that the water should not flow down to its base, was connected with the insulating stool. Horizontal pieces, *h* and *i*, were used to shelter the silk cords. The protecting device for the observer was simply a piece of brass.

On May 10, 1752, an old soldier named Coiffier, probably as ignorant as was Alibard himself of the dangers of receiving a lightning stroke *via* the rod, noting the advance of a thunderstorm determined in the absence of Alibard to experiment on his own account. Accordingly he mounted the stool, presented the wire to the rod, and obtained a fine spark; then another even more brilliant. He at once called all his neighbors, and some one ran in search of the parish priest. The latter was seen making his way to the apparatus in such undignified haste, that it was immediately surmised that the daring Coiffier had fallen a victim to his bold experiment, and accordingly the good father found himself the leader of a miscellaneous mob of villagers. Regardless of the pouring rain and hail, the crowd surrounded the machine and there in open-mouthed wonder watched the priest himself draw sparks from the rod. But both the clergyman and the soldier managed to get lightly struck—so slightly that in their absorbed attention to the sparks they scarcely noticed the occurrence until afterwards, when each, feeling stinging

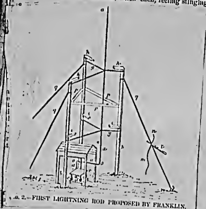

Fig. 2.—FIRST LIGHTNING ROD PROPOSED BY FRANKLIN.

hardly possible to divine. At the end of the rod there was a thread which, when not electrified, hung vertically, but which otherwise stood out at various angles. Richmann was bending over his instrument, and Solokow, an artist, was standing by, ready to sketch the phenomena which might occur. Suddenly the latter perceived a globe of blue fire, about as large as a man's fist, leap from the rod of the gnomon toward Richmann's head, scarcely a foot distant. At the same instant Solokow was violently thrown down. On

his recovering consciousness, he found the apparatus shattered into minute fragments, the door of the room crushed and thrown over, and even the woodwork of the apartment was everywhere split. Richmann was dead. The lightning had passed through his body, and made its exit by the left foot. On the forehead were a few drops of blood, although the skin was not broken. There was a blue mark on the foot and a hole pierced clear through the sole of the shoe. On the side of the body were red and blue spots, as if burned. Thus perished the first martyr to electrical science.

Among the new inventions for determining the degree to which air is electrified was that of Abbé Nollet, who made shortly the experiments at Marly-la-Ville. He devised the apparatus, as represented in Fig. 5, for leading the electricity into a room so that it may be examined. At E F

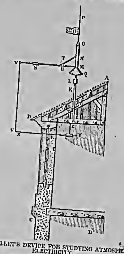

Fig. 5.—NOLLET'S DEVICE FOR STUDYING ATMOSPHERIC ELECTRICITY.

is a garret window, K is a wooden rod extending about 4 feet above the roof, and surmounted by a tin socket which receives a tube of thick glass, L M, which in turn supports a tin tube, N O. The latter, about 5 inches in length, is surmounted by an iron rod, O P. The cone Q serves to protect the glass from becoming wet by the rain, and attached just above this cone is the upper horizontal rod of the frame R V X E. The end, Y, enters the garret through one of the window panes, and is supported by the rod, Z. The collected electricity is thus led into an apartment, where it may be examined.

Fig. 4.—RICHMANN STRUCK BY GLOBE LIGHTNING.

About this period also Abbé Poncelet conceived the idea of lightning shelters, or structures in which people might take refuge during thunderstorms. He had no notion of lightning rods, nor did he believe that such could serve any protective purpose, but he proposed to make his structure of a frame of resinous wood covered with three thicknesses of waxed cloth. Inside the tent was to be lined with silk. "Suppose now" the inventor quaintly says, "that the thunder happens to fall on this little edifice, what will happen?

less than nothing. As it presents on all sides resinous surfaces, which never receive phlogiston by communication, the latter, after having leaped lightly around the pavilion and finding itself unable to attack it, will probably depart in order to pursue its ravages elsewhere." As a frontispiece to his book, Abbé Poncelet has a picture which we reproduce in Fig. 6, representing the interior of his pavilion. He himself is standing in the center withdrawing sparks from a rod which descends from the roof, while the lightning and storm clouds harmlessly surround the structure.

While Franklin was pursuing his electrical experiments in the United States, an unknown provincial magistrate named

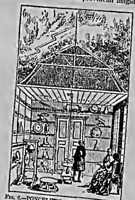

Fig. 6.—PONCELET'S INSULATED HOUSE.

De Romas was likewise making researches with the greatest zeal. He, like Franklin, suspected the analogy between lightning and electricity, and was led to the idea by phenomena of attraction, of which he was witness, caused by a

lightning stroke, which occurred in 1750. In order to produce more powerful sparks, he thought of raising an isolated conductor to a great elevation, and in this way he reached the notion of using a kite as the conductor. Here we meet one of those disputes as to priority which strew the borders of the entire road along which the onward march of invention has progressed. It is unnecessary here to recall the circumstances of Franklin's kite experiment, which De Romas claimed to have anticipated, and it will suffice to state that even, if the French investigator was the first to conceive the idea, he placed his early results on record in such mysterious and

confused language that the same furnishes but little evidence in support of his assertion. Some of De Romas' results of later dates are, however, quite interesting. In 1753 he sent up a kite of about eighteen square feet in area, but his cord remained dry and he obtained no sparks; the failure caused both merriment and mockery among those assembled to witness the experiment. Next time he oiled his kite, wound the cord with very fine copper wire, and sent the kite aloft in a thunderstorm. His arrangements worked so well that he obtained shocks which, as he expressed it, made him "feel every point in his body;" and those who doubted the matter and tried for themselves found out to their confusion that he was exceedingly right. With great intrepidity he then assumes the unknown risk of severe shocks. From a glass tube about a foot in length, the end covered with tin and connected by wire to the ground, he made an excitator, Fig. 7, by which he was enabled to obtain sparks seven or eight inches instead of scarcely an inch in length as hitherto. The noise of the discharge was audible at a distance of more than 200 feet, and even as far away as 8 feet the spider web sensation on the face could be felt. Three straws were attracted by the tin tube, danced between earth and tube for some time. Then one touched the tube, a discharge passed through it and made a hole in the ground. The straw then ran up the cord until the kite was attained, which it touched, then retreated, and so kept moving to and fro, at each contact drawing a spark. At the time neither lightning nor thunder was present. A strong ozone odor was noticeable, and the cord was surrounded with a cylinder of light 3 or 4 inches in diameter. Subsequently De Romas found that the danger in the kite experiment was greatest during the raising of the kite, as he himself repeatedly sustained severe shocks during that proceeding. Accordingly he invented a carriage on a reel on which he placed his cord and then dragged his vehicle behind him while running by silk lines, Fig. 8.

The old experiments which we have here detailed, as well as others made at the same period, have proved, as now well known, of great scientific value. They demonstrated the certainty of the fact that lightning only differs in abundance from the electricity which we can easily accumulate in conductors or in batteries.

Aug **Casualty by Lightning.** 77

The Salem (N.J.) *Standard* states that recently Mr. Henry White, a well-known resident of Lower Penn's Neck, was killed by lightning as he stood in his own doorway. He went to the door to look at the clouds, and as he looked out he placed his hand upon the water conductor, and was instantaneously struck by the electric fluid, which, it is supposed, was at that moment passing down the spout.

Nov 15 - 78

ATMOSPHERIC ELECTRICITY.—In a recent article in *Appleton's American Popular Science Monthly*, Mr. Elisha Foote argues that when escaping steam infringes upon a conductor, the electricity generated in the latter is not due to friction, as Faraday believed, but to condensation of the steam. Blasts have been accidentally exploded by the steam from locomotives enveloping the naked wires of the electric fuse, and sparks have been observed on the switch board of railway telegraph offices when locomotives vented steam against the telegraph lines near by. These cases, however, speak at least as much for Faraday's explanation as Mr. Foote's.

42

JOURNAL OF THE TELEGRAPH.

VOL. X., NO. 3. NEW YORK, FEBRUARY 1, 1877. WHOLE NO. 222.

INFLUENCE OF ATMOSPHERIC ELECTRICITY AND INDUCED EARTH CURRENTS IN TELEGRAPHY.

As long ago as 1752, Franklin demonstrated conclusively, by the well-known kite experiment, that when a thunder storm is in progress, the upper portion of the atmosphere is in an electrified condition. He has also shown that the storm breaks forth as soon as a discharge of the electricity contained in the clouds takes place, either directly with the earth or with other clouds charged oppositely. Various experiments since Franklin's time have shown that traces of electricity are to be found in the atmosphere at almost all times. One of the simplest ways of showing this is to erect a conducting rod in the air and connect its lower end to an electroscope, Peltiers' electrometer, fig. 1, answers the purpose very well.

When the sky is clear, the air is always positively electrified to a height of perhaps five feet above the earth's surface, but the electric potential at that distance is not very perceptible except with the most delicate apparatus, it increases however, with the elevation, but is not the same for any one point at different times of the day, there being maximum and minimum conditions. The former occur about two hours after, and the latter about the same length of time before sunrise and sunset.

When the atmosphere is positively electrified it acts inductively on the earth so that the latter is almost always found to be negative with respect to the former, but owing to the very great insulating properties of air the two electricities do not unite as a general thing except during thunderstorms, at such times the electric accumulation becomes so great that it is enabled to break through the insulation of the atmosphere and a discharge takes place almost instantaneously.

As regards the real cause of atmospheric electricity physicists still differ but it is generally conceded that the rapidity of evaporation, especially at sea, and the subsequent condensation of aqueous vapor in the upper air currents which flow from the poles, has something to do with the phenomenon.

Clouds are charged sometimes with positive and sometimes with negative electricity. The positive charge is supposed to be derived directly from the atmosphere by the vapory particles floating therein, and which, before condensation occupy comparatively vast fields of space. In the process of condensation or cloud formation, the electricity distributed over these extended tracts becomes concentrated within narrow limits and the clouds thus acquire large quantities of electricity of high potential. The negative charge, it is assumed, is derived from contact of the cloud with the earth. In what follows we will suppose the charge to be positive. When a cloud W fig. 2 so charged passes over a place it disturbs the electric equilibrium of all bodies beneath it, attracting the negative electricity to the parts A and B in its immediate vicinity and repelling the positive to the more remote parts D and C. As the elevation of the objects above the earth's surface and their conductivity increase the accumulation or charge which they receive becomes greater. It is therefore obvious that a metallic conductor such as a telegraph line whose termini are in communication with the earth will attain its maximum charge sooner than other and less elevated objects. Men and beast do not, as a general thing, perceive any change of the neutral state from this inductive action because it is produced in a gradual manner by the nearer approach of the cloud. When the latter disappears without the establishment of equilibrium between W and A B by direct discharge, the negative electricity at A

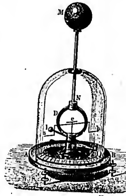

Figure 1.

B gradually reunites with the positive at D and C, and a telegraph line LL, between these points is traversed by a current.

If the electricity of the cloud W is suddenly removed as for instance by a discharge into a neighboring cloud these currents become strong enough to make themselves manifest by their action on the apparatus and it sometimes happens that they are so frequent as to greatly interfere with, or even altogether prevent the working of the line.

From numerous careful experiments it appears that telegraph lines are almost always traversed by currents due to actions of this kind, even in clear weather, but at such times they are too feeble to be observed unless special means are taken for that purpose. They are more marked, after some days of hot weather, a sudden change of temperature, or at the beginning of a rain or hail storm.

The disappearance of a heavily charged cloud from any given place is not, in general, so rapid as its appearance because of the attractive influence exerted between the positive electricity of its own charge and the induced negative charge on the earth's surface below it; this influence moreover, tends to draw the cloud nearer and nearer to the earth and at the same time causes the opposite charges to concentrate within more narrow limits until finally the potential becomes great enough to break through the intervening air stratum, as before remarked, and a flash of lightning occurs.

In such cases the greater part of the electricity of the cloud is discharged and the electric equilibrium of the earth below renewed, as shown by the momentary current in the line L L', fig. 2, even though the latter is not in the direct line of the discharge. Any remaining portion of charge in W, if sufficiently large, again acts inductively on the earth, and thus forms the necessary conditions for another flash, sometimes, indeed, for many more of them, until the cloud becomes completely discharged and the storm is passed. It is evident, from the above, that an electric disturbance always precedes the appearance of lightning. This is especially marked in elevated objects, which, as such, soonest reach a limiting charge, and also, by reason of their comparatively low resistance, offer a ready path for the combination of the opposite electricities of the earth and clouds. Telegraph lines fulfil the last condition very perfectly, and being also very extensively developed, thus become particularly liable to being struck by lightning.

The disturbing influence of lightning on a telegraph line is well known. If the wire itself or any object in its vicinity is struck interruptions or damage to the wires and instruments of a more or less serious nature will follow unless special precautions have been taken to guard against such results. It is also a fact that slight interruptions are apparent at a distance of even three or four hundred miles from the place where the storm is in progress. We thus see that it is possible by merely observing whether the disturbance gradually increases or decreases, to determine when a storm is approaching us or passing in the opposite direction. When, however, the storm is near and heavy, large quantities of electricity of high tension instead of following the route of the wires alone, frequently enter the station and pass in the form of sparks from the line and neighboring metallic parts to earth by way of the ground wires or such other means as may be available. Sparks have been seen to pass in this manner from one object to another although the latter were some yards apart. In all such cases fusion of the wires and other damage is sure to follow.

From the preceding remarks is is evident that all of the general phenomena of interruptions from atmospheric electricity may be classed under the four following heads:—

1st Interruptions produced when the line is in the

44

A curious variety of the globular form of lightning has been described in a letter from M. Blanc, of Venice, read to the French Academy. About midnight, on the 21st of March, he noticed the east was lit up with flashes, unaccompanied by thunder. Taking a good position, he saw a bank of dark clouds, with several small fleecy clouds moving above it in various directions. The appearance was like that of a dense mass in ebullition, with light scoriæ carried hither and thither on the surface. Over one such dark mass, which was greatly agitated, balls of fire appeared to rise from an invisible centre, moving in all directions, and after a course of 6 to 10 degrees, bursting silently with a dazzling brightness. Their apparent diameter, at a distance of 18 kilometres, was about 1 degree; their colour reddish, sometimes yellow, but always white at bursting. Their horizontal course was parallel to the plane of the clouds. They had the aspect of immense soap-bubbles, and seemed of similar lightness. The phenomenon was reproduced about three or four times in a minute. The motion of the balls seemed comparatively slow.

Apr 77

The Destructive Effects of Lightning.

The amount of destruction of life and property by lightning, or rather electrical discharges, has been very great throughout the world.

It is estimated that at least 45 persons are killed annually by lightning in this country. The average number of deaths by lightning has been 22 in England, 9 in Switzerland, 8 in Belgium, and 75 in France. In France alone, during a period of thirty years, over 10,000 persons were smitten, of which 2,252 were instantly killed. Eighty were wounded and 9 killed during one thunderstorm at Châteauneuf les Moutiers in 1861, and within one week, when the air was highly charged with electricity, thirty-three fearful flashes of lightning were observed, each bringing death to some victims.

During the sixteen years between 1799 and 1816, 150 vessels of the British navy were struck by lightning; 73 men were killed and 138 injured, and the loss of materials amounted to over a million dollars; but since the system of metallic conductors, adapted for vessels, devised by Sir W. Snow Harris, has been applied to the vessels in that navy, the losses and damages by lightning have almost entirely ceased, although the number of vessels has been greatly increased.

In Fuller's Church History it is stated that "scarcely a great abbey in England exists which once, at least, was not burned down by lightning from heaven."

On the night of April, 1718, twenty-four steeples were struck along the coast of Brittany; and on the 11th of January, 1815, twelve steeples suffered a similar fate in the Rhenish provinces.

On the 27th of July, 1759, lightning burnt all the woodwork of the great cathedral at Strasbourg; and on the 14th of August, 1833, it was struck three times within a quarter of an hour, and so much damaged that the repairs cost about $6,000,000. In 1835 lightning conductors were placed upon the building and steeple, and since then it has not been damaged whatever by lightning, although discharges have on several occasions occurred in line with the top of the steeple, which is 437 feet above the ground.

On the 18th of August, 1769, the Tower of St. Nazaire, at Brescia, was struck, and the subterranean powder magazine, containing 2,070,000 lbs. of powder, belonging to the Republic of Venice, was exploded. One sixth of the whole town was laid in ruins and the rest very much injured, and about 3,000 persons killed.

On the 20th of June, 1807, the powder magazine of Luxembourg, containing 28,000 lbs., was struck, and besides about 30 persons killed and 200 injured, the town was ruined.

Explosions and large fires, in[illegible] a great [illegible], have become rather frequent in this country, owing to the iron tanks used for the storage of petroleum being struck by lightning. From March to August, in 1876, over 10,000,000 gallons, and on April 10, 1877, over 2,000,000 gallons of oil, and the village of Troutman, were destroyed in the oil regions of Pennsylvania.

Some of the thunderstorms which have prevailed in this country have been very terrific and destructive. During August 14th, 15th, and 16th, 1872, portions of New York State and the New England States were visited by some of the most terrific thunderstorms ever experienced, during which over 200 dwellings were struck and damaged, about 16 persons were instantly killed, and 160 stunned. Quite a number of barns, with their contents, hay and cattle, were also struck, fired, and consumed. Cars, while running on some of the railroads, were surrounded by a vivid electric light, but no passengers were injured, although they were greatly alarmed. Telegraph wires were melted by the half mile, telegraph instruments broken, and poles shattered in all directions. One of these storms occurred at midnight, at Arlington, Mass., August 14th, in which brilliant streams of electricity darted across the sky in every direction, and the thunder which followed was constant for a period of thirteen minutes, without the intermission of an instant of silence. Three hundred and thirty-one discharges were counted in seven minutes by an observer, and each discharge was followed by loud and sometimes rattling reports, whose reverberations rolled through the heavens in an endless procession of majestic and terrific sounds. During this scene, the moon, which was about half an hour above the western horizon, was visible, but so magnified, through the haze and vapor, as to appear like a brilliant flame suspended in the sky. For a period of twenty minutes the scene was one of grandeur and sublimity rarely witnessed.

In the States of Illinois and Iowa, and the prairie country west of the Mississippi river, thunderstorms are generally more terrific, and more lives have been lost there from the effects of lightning than in any other section of this country. Owing to the said country being level and devoid of trees, the equilibrium between the electricity of the atmosphere and that of the earth is principally restored by disruptive discharges.—*Spang's "Treatise on Lightning Protection."*

It is now exactly a hundred years since the first lightning conductor was placed in Berlin. Franklin's discovery was made in 17[illegible], and in 1777, on recommendation of Professor Sulzer and M. Gerhard, it was applied to the (then) magazine of military equipments in Kö[illegible]ker Strasse, No. 11, built under Frederick the Great, in 177[illegible]. At present there is a Ministerial order which regards the application of lightning conductors to (German) Government buildings as unnecessary. In France a different view is taken; every public building—even the school—is provided with a lightning-rod.

Sept 77

LIGHTING STREET LAMPS BY ELECTRICITY.

July 77

MAYOR PRINCE, Alderman Slade, and other gentlemen of the Boston city government, have been here inspecting the system of lighting the street lamps by electricity, which has been successfully introduced by the Electric Lighting and Telegraph Company. It should be stated at the outset that the system here in use is entirely different from those which have been tested in Boston and other cities without success. Hitherto attempts have been made to operate the stop-cock connected with the lamps and light and extinguish the gas by means of electricity. This method proved a failure chiefly because the faulty working of the stop-cock, which fact of course vitiated the whole system. The objections to this plan have all been obviated by the Electric Lighting Company. Instead of attempting to operate the stop-cock by the agency of electricity, compressed air is used, thus making the turning on of the gas and lighting it by electricity two entirely separate and distinct operations. By this process all the operations are conducted in clock-work order, and the failures in lighting the lamps in this city for six months have been less than one-fifth of one per centum, and the failures in extinguishing them have been less than one-fiftieth of one per centum, reckoning in both these estimates all defects arising from the clogging of the gas burners, leakage of pipes, breakage of lanterns, and other mishaps which are inevitable even under the system of lighting by hand.

The process by which the lamps are lighted and extinguished is exceedingly simple. All the lamps are connected with a battery by an underground wire running through an airtight tube, which is attached to an air-pump. This tube is half an inch in diameter, and is laid fifteen inches below the surface of the streets or sidewalks. By a simple operation of the air-pump the stop-cocks connected with all the lamps are opened or closed, and by a single touch of the key connected with the electric battery the lamps for a circuit of any length, be it one mile or one hundred, are lighted in an incredibly short space of time. If, for any cause, a lamp in the circuit fails of lighting or extinguishing, an indicator connected with the battery points out the number of the lamp so failing and another touch of the key remedies the defect at once. These failures are of such exceedingly rare occurrence, however, as has already been shown, that but little or no importance is attached to this feature of the system. The cost of keeping the apparatus in running order and in good repair is scarcely appreciable, a matter of thirty or forty dollars being sufficient to keep up the works for a year. The services of one person amply suffice for conducting the entire work, and the only extra labor required is for keeping the lamps properly cleaned.

The company agree to furnish the battery, the air pump, laying the underground wires and the entire apparatus necessary for conducting the work at an expense of $50 per lamp. The company guaranteed to effect an annual saving to the city of $15,000 for the two thousand lamps in the city, or a *pro rata* saving on any smaller number of lamps that were given them. This necessitated an actual saving in the amount of gas used and in the labor of lighting of $7.50 per lamp, but as the contract covered six months only, and called for the lighting of only two hundred and twenty of the two thousand lamps, the company was thus bound to show a saving of $825 for the period covered by their contract or forfeit all claim to reimbursement. This saving appears preposterously large at first thought, but when it is remembered that the services of lamp-lighters are dispensed with, and what is still more important, that the lamps are all lighted in an instant when it is dark instead of half an hour or more before gaslight is required, as is invariably the case under the method of lighting by hand, the guaranty appears a reasonable one. That the experiment has been a successful one in every respect, and that the company has made good its boast, is shown by the fact that upon the expiration of the six months the city paid the company for its work, and an offer, based on precisely similar conditions, to light five hundred more lamps, is now before the city government, and will doubtless be favorably acted upon. A saving of over $3.25 per lamp was realized by the city during the six months.—*Providence Letter to Boston Post.*

LIGHTNING CONDUCTORS. 77

[13136.]—AFTER all that has been written about lightning conductors and lightning, the general information on the subject is very meagre and very unsatisfactory, from an almost total absence of any certainty. Are the thin wires used on chimney stalks and church steeples in this country any protection at all? Can they be said to conduct the electricity when struck, or do they act by preventing the building to which they are attached from being struck? I have just seen the following description of the way the Americans "protected" a portion of their Centennial Exhibition, and it will be seen how very closely they approached to Prof. Clerk Maxwell's dictum of sheathing a building in copper (at least I think that was what he proposed). The tin roof of Machinery Hall has an area of 14½ acres, and is utilised as a lightning conductor in this manner. Rising above the roof are 100 wood terminals (used as flag poles), to each of which is attached a copper wire rope ½in. in diameter, its upper end rising a few inches above the top of the pole; at its lower end the wires are spread out, and 3in. of its length is firmly soldered to the tin roof. Earth connections from this massive roof conductor are made at ten different places by soldering one end of copper ropes to the tin roof, the other end being firmly attached to 8in. city water pipes in the ground. Thus it will be seen that every square foot of this huge building is covered and thoroughly protected by an ample conductor; and it is believed there is no building in this country so perfectly protected. The total cost was only one-tenth the amount requisite to protect it in the usual way with rods. The tin plates are, I imagine, "terne"—that is, thin sheet-iron coated with a mixture of lead and tin—and, I presume, would thus be practically as useful in conducting electricity as copper. The latter metal, if it were not so dear, would make a handsome, not to say splendid, roof-covering for churches; but why are not "terne" plates used in this country? Is it from the acid in the air and rain, or what, that they are [illegible] to be unsuitable? It is always either zinc or lead, and the latter, owing to the "purification" [illegible] it undergoes nowadays, is falling into disuse. I have seen the following recommended for "earth connections," but then I am told that a piece of iron pipe will do just as well:—Extend the lightning rod underground, say 20 or more feet from the building; fasten and solder to its end a sheet of copper 2 by 4 feet; dig a pit 3 by 6 feet, and 4 to 6 feet deep; put 2in. in depth of finely broken charcoal over the bottom, then put in the plate and rod, with another layer of charcoal and a few inches of earth; then fill up to surface with loose cobble stones, leaving it so that the rainfall can freely find its way down to the copper plate; water from the roof may be led into the pit.

This is plain and definite, if one could rely upon it; but it wants completing by information about the "rod." Of what should that consist? Will iron gas-pipe do, or must it be copper, and what should the diameter be? I suppose it is nonsense to say that a private house requires only a thin wire while a church tower would necessitate a thick rod, for it seems to me the lightning flash is not proportioned to the size of the building struck.

[30239.] — Thunderstorm.—Lunar Phenomenon.—To HUMPHREY BECKHAM.—I have only just now seen your question about a lunar phenomenon, under head of "Thunderstorm," in MECHANIC of August 24th, and write to say that I have several times, but at long intervals, seen the "chromatic annulus," or as I have generally called it, in speaking of it, "prismatic ring," exactly as described by you, round the moon here (county Limerick, Ireland), and I once saw it double, like a double rainbow. This was very beautiful, the inner ring being very vivid and distinct, but as remarked by you, the blue and violet tints predominating more than in the rainbow. Like you I have never read or heard anything of this very beautiful phenomenon, which is quite different from the slight tinge of prismatic colouring sometimes seen in the ordinary halo round the moon previous to wet weather. I once saw a lunar rainbow. It was a distinct and perfectly-formed arch, but showed no prismatic colours. It is a long time now since I last saw the prismatic ring round the moon, and I am sure it is of very rare occurrence. I have, perhaps, seen it three or four times in, say, 40 years. P.S.—My son has just told me that he saw a beautiful lunar rainbow last July at Kilkee, on the county Clare coast, and that it was perfectly white. He has never seen the prismatic ring.—G. J. H.

[31026.]—Gas Lighting by Electricity.—The apparatus to which "Agricola" refers was an American patent, and the cause of the electricity was friction. It was, in fact, an electrophorus. I don't know that they are anywhere offered for sale in England; but, if "Agricola" particularly wants one, by writing to me I can tell him where he may get one. It acts first class except in damp or wet weather.—W. J. CHADWICK. 78

77 THE TELEPHONE IN GERMANY.—According to a letter, which appears in *The Times* from its Prussian correspondent, it appears that several hundred specimens of improved telephonic apparatus have been ordered by the German Central Telegraph Office, to be employed for local purposes and experiments. The new apparatus, as manufactured by Messrs. Siemens and Halske, presses magnetism into the service of sound. A suspended magnet being by the human voice caused to vibrate, the several oscillations are, by means of rope wire, transferred to another magnet suspended at a distance. The tremulous motion of the air at one point being thus exactly repeated at the other, the words spoken at the receiving station are audibly transmitted to the place of delivery. The instrument is only a few inches in size, is very cheap, and may possibly be destined to work a revolution in telegraphy. Prince Bismarck's study at Varzin has been connected with the Foreign Office at Berlin by a telephone apparatus. The demand for these instruments is said to be very large.

LIGHTNING-CONDUCTORS.

ELECTRICITY—that subtle force of which we know so little, and yet the effects of which are frequently so manifest—of two or more channels, selects the best; and when it finds a sufficiently conductive passage, lightning is disarmed of all destructive energy. This is the principle of the lightning-rod, introduced by Franklin in 1752, and not materially altered in its main features from that day to this. A good deal has, however, been discovered as to the proper arrangement of lightning-conductors, and the best method of applying them to buildings, and of connecting them with the earth.

Various Governments have, from time to time, appointed committees on this subject. The Paris commission, which sat in 1823, determined the minimum sectional area of an iron conductor as a square of 15 millimetres (about 3·5ths inch) inside, and this they considered sufficient under all circumstances. The instructions issued by the Inspector-General of Fortifications for Great Britain, and which have been adopted by the American and other Governments, may be summarised as follows:—The lightning-conductor should be continuous in all its parts, should be placed in close contact with the building to be protected, not being insulated by glass or earthenware, and should be led several feet above the highest point of the building. All piping and metal on roofs should be connected with it, and when more than one conductor is required, they should all be connected together, either above or below the surface, the piping and other masses of metal in the line of probable discharge being also placed in communication. The conductor should be properly connected with the earth, terminating in a large metal surface, and lie sufficiently deep in it, according to the degree of moisture in the soil, as to secure the complete dispersion of the electricity.

With regard to powder magazines, the War Office instructions enjoin that when large quantities of explosive substances are stored in underground magazines, such as the main magazine of a

FIG. 1.

fort, they shall, as well as ordinary magazines above ground, be provided with lightning-conductors. After providing that the flagstaff should have a conductor, they add: "An iron building is of itself a good conductor, but where it is covered with non-conducting substances, such as asphalte and concrete, it is necessary to provide rods or points projecting above the asphalte, and to have a proper connection with each."

Messrs. R. S. Newall and Co., whose wire-ropes and telegraph cables we noticed lately, have also devoted a considerable amount of time and attention to lightning-conductors and the method of fixing them. They are of opinion that, for small buildings, a simple conductor will generally be found sufficient, but it should not have a less conducting power than a ½-inch copper-wire rope. This should be fitted to the end of the building, the point rising about 2 feet above the chimney. A horizontal conductor should also be added along the ridge, fixed close to the building, and having no joints, if they can be dispensed with, throughout the whole of its course. Special attention must be given to the chimneys of all buildings, because they are virtually tubes lined with a carburised conducting material, the more so if there are fires below, sending up a current of warm air, which is an excellent conductor of electricity. For larger buildings, however, a rod should be placed at each end and at intervals of from 12 to 15 yards along its length, the roof and chimneys being protected as before described. It is important to place any metal that may be on the roof in direct communication with the conductor; instances are on record where a building has been struck at some distance from the lightning-conductor. A building 40 feet long should, as a rule, have two conductors; and if 100 feet or more, three conductors. Larger and more complicated buildings should be protected on similar principles, having rods at each corner and rope along the ridge, all being properly connected with the earth. Fig. 1 of the accompanying engravings shows a house thoroughly protected against the lightning discharge on the above system; the black lines on chimneys, ridge, eaves, &c., show the conductor.

Water mains provide the best earth-connection, if conductors are properly secured to them. In the absence of these, and where there is no drain or well of water near, or where the soil is clayey or rocky, the conductors should be surrounded by a quantity of coke to increase the contact

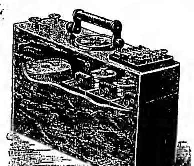

FIG. 8.

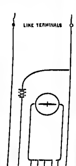

FIG. 9.

and prevent the conductor, if of iron, from rusting. Carbonate of soda may also be applied with advantage. It is a very important matter, if the conductor is in more than one length, that the joints should be carefully made; if it consists of a rod, the joint should be soldered, and if of cable the ends should be carefully spliced.

In applying lightning-conductors to chimney-shafts and public buildings, the same rules are to be observed, though the varying circumstances of each, the extent and prominent parts above the roof, must be studied, while, at the same time, the outward appearance of the structure should be preserved. In these cases a conductor of greater capacity is generally used, and the joints should be very carefully made. In ornamental constructions the lightning-conductors should invariably form part of the original design, and not be added subsequently, as if in consequence of an afterthought. In the Albert Memorial, Hyde Park, the conductor, supplied by Messrs. Newall, is carried down through the centre of the column, so as not to destroy the symmetry of the structure.

The lightning-conductor consists of three parts: the rod, which is carried up above the highest part of the building; the connection with the earth; and the intermediate portion uniting the other two.

We engrave (figs. 2 and 3) alternative forms of rod, manufactured by Messrs. Newall, who give a preference to the simple rod terminating in a sharp point; though the cluster of points is also supplied in deference to an opinion shared by some that this form affords a greater chance of dissipating the lightning-cloud. These are made of copper, sometimes with a tip of solid platinum. The rod itself is from 4 to 10 feet in height, according to circumstances. Fig. 4 shows an enlargement of the clip where the joint between the rod and intermediate conductor occurs; and fig. 5 an additional support to the rod higher up, if required.

This intermediate portion should consist of copper, and may be in the form of a ribbon or a rope; but a copper-wire rope is much to be preferred, on account of its easier adaptability to the irregularities of a building. Fig. 6 shows a holdfast to be driven into the wall for securing the rope, and fig. 7 a guide intended to be built into the corner of a square chimney for the same purpose. These are made of copper if a conductor of that metal is employed.

Great difference of opinion has existed as to whether the conductor should be insulated from the building or not; but there is strong reason for believing that insulators, instead of being a protection, are positively a source of danger. They become covered with moisture during a storm, and are, therefore, of no effect, moisture being a good conductor of electricity.

FIG. 2.

FIG. 3.

FIG. 4.

FIG. 5.

FIG. 6.

FIG. 7.

With regard to the best metal to be employed, the relative conductivity of the metals to electricity is given as follows:—Lead, 1; tin, 2; iron, 2½; zinc, 4; and copper, 12. The last-named is the best conducting substance of all the ordinary metals, as, besides its high conductivity, it is very durable, and not liable to oxidation. When, however, conductors are exposed to abrasion or torsion, or are liable to be stolen, and where attendant circumstances are unfavourable to corrosion or oxidation, iron may be substituted; but proportionately larger dimensions must be given to the conductor, to compensate for its smaller conductivity. Iron has this advantage, that its fusing temperature, 2786° Fah., is so much greater than that of copper, 1993°; but in all other respects copper is preferable. An equal amount of conducting power may be obtained in iron and copper for about the same price; as the smaller cost of the iron makes up for its lower power of conduction.

The proper arrangement of the third portion, viz., connection with earth, is certainly not less important than the other two. If it should terminate in a dry sandy soil, the lightning-conductor would be worse than useless. The best arrangement is that the conductor should terminate in a well or large body of water, as the water, having various ramifications in the soil, presents the best means of dispersing the electricity. Where this is impracticable, the conductor should be continued into deep ground; and, as sand, shingle, or other light dry soil, does not form a good earth-connection, the rod should be led through these strata until water or a permanently deep soil be reached. The conductor should be led into moist ground, by means of a trough extending to at least 18 inches below the surface, and in which there is a considerable length of metal—the War Office authorities recommend as much as 30 feet of metal—or a plate 4 feet square should be placed in actual contact with the moist earth. In the case of very dry sandy soil, the trench should extend from the foot of the conductor to distances of from 10 to 40 yards, according to the amount of moisture; and it is useful to lead the water from the roof of the buildings, through the down pipes, over the ground in the vicinity of the earth-connection, or into the trough just referred to.

In applying lightning-conductors to vessels, it must be borne in mind that a ship at sea is more liable to receive great discharges of electricity than buildings on land, for the reason that, while on land the intensity is generally spent on more than one of the objects within its range, the vessel is often the only object intervening between the clouds and the earth, and it receives the full force of the lightning discharge. For this reason a conductor of greater capacity is required. All masts are equally liable to be struck, whether one of them be protected or not, many cases being on record of damage occurring to the foremast of the ship while the mainmast was protected. It follows that each mast should be provided with a lightning-conductor, which should have a sectional area equal to at least ⅝-inch diameter. The copper rope is also found the most useful form of conductor in this case, as it may be obtained in any length, is simply applied, and yields to every movement of the vessel. The method of fixing recommended is to carry the ropes down the backstays, and nail them to the ship's sides. Formerly the link or chain form of conductor was employed, but the discontinuity of the parts formed a material objection to its use. When struck by lightning, the expansive and heating effect at the joints was so great that the metal became fused, and in many cases the links were broken.

In a previous paragraph we have spoken of the importance of terminating the rod in "good earth." Upon this depends the value of the lightning-rod. Most of the accidents which have taken place where conductors have been on the building, can be accounted for by insufficient earth-connection. A lightning-rod when fixed should be tested by a galvanometer, and the earths should be tested at least once a year. A very portable galvanometer for testing lightning-conductors has recently been introduced by Mr. Richard Anderson, M.S.T.E., F.C.S., London, manager to Messrs. R. S. Newall and Co. The wood-cut (fig. 8) shows the arrangement of the battery, galvanometer, and resistance coils. The battery consists of three cells, and is a modification of the old manganese cell, in which the carbon and oxide of manganese occupy the outer, and the zinc plate the inner or porous cell. By this arrangement the surface of the negative element is greatly increased, and hence a more constant current is obtained on account of the battery not polarising so rapidly as in the old form. Another advantage of this arrangement is that the cells can be almost entirely sealed up, the air-openings being made within the porous cell. In the centre of the lid of the box is placed the galvanometer with a "tangent" scale. On the left are two terminals, by which to connect the conductor to be examined. On the right hand end of the lid, are placed five keys, marked, respectively, L, B, 1, 2, 3. Under B is one pole

of the battery, so that by depressing this key, as will be seen by the following connections in the diagram (fig. 9), the battery current is sent through the galvanometer direct. If, however, we depress key No. 1, we connect the battery with the galvanometer through a known resistance—key No. 2 has a larger resistance, and No. 3 still larger. The fifth key, L, closes the circuit within the limit of the instrument, but on being depressed opens it, and includes the line or conductor placed between the two terminals at the other end. Battery key also must be pressed down. By this arrangement it will be seen that the resistance of the line or conductor may be compared with the known resistance connected with any of the keys Nos. 1, 2, 3, or any of these resistances may be included with that of the line, so as to get a convenient deflection of the galvanometer needle. In the case with the battery is a bobbin of insulated wire for connecting the instrument with the conductor and earth to be tested.

Among the works and buildings provided with lightning-conductors by Messrs. Newall are those of Messrs. Maudslay, Sons and Field; Messrs. Ransomes and Sims, of Ipswich; the Great Northern Terminus, King's Cross; the Pumping Station, Commercial Docks; most of the ship-building works on the Clyde; and those of the London gasworks, breweries and hospitals; several London Fire Brigade Stations; the Alexandra Palace; the Royal Aquarium, Westminster; the Monument, Fish Street Hill; and Her Majesty's Laundry, at Richmond. We notice that the firm have been awarded a gold medal at the Cape Exhibition this year.

Remarkable Form of Lightning

I am able to confirm the fact that lightning occasionally takes the "punctuated" form described by Mr. Jamie in NATURE, vol. xviii. p. 260. Some forty years ago, in a thunderstorm which I had the good fortune to witness at Ampton, in Suffolk, the lightning (with heavy rain) was almost incessant for half an hour or more, and about a quarter of the flashes (speaking from memory only) presented this unusual appearance. I have often looked out for it since, but only once with success, and then it only showed itself in a single flash out of many. On both occasions the "punctuated" flashes presented in general a curved or sinuous line without sharp angles; and two or three of them in the first-mentioned storm *appeared* to my eye as closed curves, one an almost perfect figure of 8; but their dazzling brightness made it impossible to speak to this with certainty.

London, July 8 78 — E. J. LAWRENCE

[33340.]—**Equatorial and Lightning.**—It would be desirable to connect the top of the pillar to the exterior of the observatory, and to provide there an ordinary conductor point. The pillar, of course, to a certain extent, invites a discharge, if it is a tall one, and will do so still more if properly connected to earth; as a consequence, some injury might occur to the observatory roof. The danger which I referred to in previous reply would be at the foundation. The pillar providing a shorter path than the air, tends to collect the electricity into that path, and then at the foot of the pillar there would be a violent discharge, and possible destruction of the foundation, and overthrow of the pillar, which a good earth connection would entirely prevent. If a good connection is made, it is of no consequence whether the wire is attached to the stone pillar or not, but it is always best to connect the conductor as much as possible to every part of an edifice it is meant to protect. There need be no difficulty about the revolving top, as a sliding contact piece, such as two tubes one within the other, could be used.—SIGMA.

ON LIGHTNING CONDUCTORS AND ACCIDENTS BY LIGHTNING.

By RICHARD ANDERSON, F.C.S., Member of the Society of Telegraph Engineers.

Abstract of Paper read before Section A of the British Association, August, 1878.

At the present time at least one-half of all the public buildings, including the churches and chapels, of Great Britain and Ireland are without protection against lightning. As to private houses, it is safe to assert that not five out of every hundred have lightning conductors.

According to the reports of the Registrar-General, the number of deaths from lightning in England and Wales during the eight years from 1869 to 1876 reached a total of 182.

According to the report of Dr. Engel, Director of the Statistical Bureau of Berlin, the number of lives lost during the same period in Prussia was 819.

The terrible losses, both of property and human lives occasioned by lightning, are mainly due to three causes, namely: first, in not providing any lightning conductors at all; secondly, in not placing them in the right position, or in sufficient number to cover a given area; and, thirdly, in not having them regularly tested, so as to ascertain their constant efficiency. Even some of the first cathedrals of England, such as Peterborough, have no lightning conductors whatever, while others, supplied with them, Windsor Castle for example, are insufficiently protected, as is apparent to any competent observer.

If the entire absence of lightning conductors is the most prevailing cause of the still exceedingly great number of casualties occasioned by lightning, that of ill-placed or insufficient conductors is another deserving much attention. The mischief done in this case is not only that the conductor gives a false security, but that, should the dwelling on which it is placed be struck by lightning, it leads to the belief that the wonderful scientific discovery of Franklin is nugatory, or at least uncertain in its action. A case of the most instructive kind, in which a house with a proper conductor fixed on it was struck and damaged by lightning, came under my own observation quite recently; a heavy thunderstorm passed over it, and the electric discharge fell on one of the towers, knocking down part of a crenellated wall, not more than three yards from a lightning conductor, and then passing off without doing further damage. The conductor being new and in good order, it seemed at first sight a very extraordinary case; but the mystery of it was soon explained by an examination of the premises, which I undertook. I found that the roof of the tower on which the lightning fell was covered by a solid mass of lead, of unusual thickness, connected at one end with a large iron water-pipe about four inches in diameter. In this case the electric force, to get to this rival conductor, heavier in metal than the one designed for the purpose, and therefore offering the best road earthward, had to smite the brick wall in its way, and having done this, it went down the iron water-pipe into the ground, doing, as already mentioned, no more damage. Had the actual conductor either been larger, that is, heavier in metal than it actually was, or had it been connected with the mass of lead in the first instance, the lightning could never have struck the house. The incident forcibly illustrates the necessity of leaving the design and erection of lightning conductors to no others but those who have made a thorough study of the subject, since the work is not by any means so free from complexity as is commonly believed.

The third cause is the utter neglect of the conductor, when once it has been put in its place; other repairs to all sorts of public buildings are regularly executed, but the lightning conductor is taken no notice of and is never tested.

Having drawn attention to the chief causes of the numerous and fatal casualties caused every year by lightning, I have only to add a few words of advice as to how they might be prevented, or at least greatly diminished. First of all, I think it most desirable that public recommendation should be made, by local and other authorities, to place lightning conductors on all exposed or high-lying buildings, whether public or private, as well as on those standing near woods and on moist ground. It might be well worth the trifling expense to place simple conductors also against trees in parks, under which there are benches, or where persons are likely to gather during a thunderstorm, they forming a prolific source of fatal accidents. Above all, no church, chapel, school, prison, or other large public building, ought to be without one or more lightning conductors. But if it is necessary to greatly multiply lightning conductors, it is equally so that they should be planned, erected, and also periodically tested by competent persons, with scientific as well as practical knowledge of the work. The testing should take place at regular intervals, perhaps best in the spring, before the advent of the summerly thunderstorms, and it should likewise be made whenever a building has been undergoing repairs which may have damaged the conductor. To show the importance of constantly testing even the best laid conductors, I can cite another instructive case where a house was apparently well protected. On the 19th of August, 1876, shortly before midnight, a heavy stroke of lightning fell upon a mansion near Kew Bridge, Middlesex. The electric force destroyed the top of a large chimney, knocking off part of the coping, not more than two or three feet from a lightning conductor, to which it then flew, making its way down to the earth, but not without causing the greatest disturbance all along its path—lifting up, among others, some heavy marble toilet tables in bed-rooms some six feet distant on either

Comptes Rendus Hebdomadaires des Séances, de l'Académie des Sciences. No. 3, July 15, 1878.

Remarks Concerning the Influence of Atmospheric Electricity of Low Tension upon Vegetation.—M. Berthelot.—Referring to M. Grandeau's paper "On the Influence of Atmospheric Electricity upon the Nutrition of Plants" (*Comptes Rendus*, lxxxvii., No. 2), the author recalls the analogy of the result with his own experiments on the formation of nitrogenous matters under the influence of atmospheric electricity. Hitherto in agricultural chemistry there has been understood under the name of atmospheric electricity merely the formation of nitric and nitrous acids and their ammoniacal salts, produced by the passage of lightning, without having any idea of the direct reactions which may come into play between plants and the atmosphere. Yet these latter seem to me the more important, the smallness of the effects being compensated by their duration and by the extent of the surfaces influenced.

THUNDERSTORMS.—We have experienced this year a succession of extraordinary thunderstorms, accompanied by an excessive downpour of rain. Had our telegraphic society been duly organised, the opportunity of a fairly thorough investigation of these phenomena would not have been lost. We would humbly suggest to the Society of Telegraph Engineers that sub-committees of investigation should be formed to carry out experiments and record observations upon various phenomena connected with electrical subjects. The late Professor Henry suggested to the American Electrical Society that it should collect and preserve information relating to thunder storms, and also prepared a series of questions as a contribution towards a more complete series to direct attention to special points of inquiry. These questions may prove useful in scientific investigations, and we therefore append them to this note. *Particulars of the Storm*:—(*i.*) Give the number and time of occurrence of thunder storms, so as to show their distribution through the months, days, and hours of the year. (*ii.*) Note the point of the horizon in which the storm generally arises in any given locality, and the point to which it tends. (*iii.*) Observe whether it usually divides into two storms at any point; if so, what is the topography of the surface below? (*iv.*) Determine the width of the storm from the extent of the surface covered by rain, and also, if possible, by means of the telegraph, the length of its path. (*v.*) Note the condition of the air before and after the storm, as to temperature, moisture, and pressure; also the temperature of the water which falls. (*vi.*) Give the direction of the wind previous to the beginning of the storm, during its continuance, and after its ending. (*vii.*) Observe whether a calm precedes the violent part of the storm, and whether in front of it a curtain of dust is raised to a considerable height in the air. (*viii.*) Note the number of seconds the sound of a discharge continues, which will give approximately the minimum length of its path. (*ix.*) Note the time between the appearance of the flash and the hearing of the thunder, and also the angle of elevation; these will give approximately the height of the cloud. (*x.*) Ascertain whether any hail accompanies the storm; if it does not, whether it falls along in two tracks, or in one. In the former case, give the distance between the tracks. Give the size and character of the hail, whether it consists of an agglomeration of crystal, or of rounded masses stratified with clear ice and snowy concretions, and whether it contains in some cases small particles of dust or sand. (*xi.*) Note the number of discharges between the different parts of the same or different clouds, and also between the cloud and the earth. The former will probably be more frequent than the latter. (*xii.*) Note the colour of the lightning, particularly if it be violet, which will probably indicate a cloud of great elevation. *B. Effects of the Electric Discharge*:—(*i.*) State what kind of trees are struck, and on what parts of the tree the effects are most apparent—on the branches, or the trunk. (*ii.*) What are the mechanical effects observed in the tree; is it torn asunder laterally, or is it broken transversely to the axis, or both. (*iii.*) Was the tree green or dry? (*iv.*) When a house is struck, state if it had a lightning-rod, and, if so, give its character and especially its connection with the ground. (*v.*) Mention the part of the house struck; if the chimney, was there fire in it at the time? Give the path of the discharge through the house, and its relation to conducting metals? (*vi.*) Note the inductive effects of the discharge in producing sparks and flashes between different objects within the premises. (*vii.*) If the discharge passes through metallic conductors and disintegrate them, note any appearance which might tend to indicate whether the effect is produced by heat or by repulsive energy imparted to the atoms at the moment of the discharge. (*viii.*) If the discharge takes place between two surfaces, note if there is any apparent transfer of material from one to the other. (*ix.*) Note any peculiarity of odour that may be observed. All mechanical effects produced by the discharge should be mentioned, and notes should be made as to whether they are not in most cases produced by a violent repulsive energy given to the air in the path of the discharge, and whether the effects are greater in the direction of the axis of the discharge than in that at right angles to the same. (*x.*) Note the effect upon man and animals; whether a part of the discharge passed through the body, or whether inductive shocks were felt.

THE ELECTRICIAN, JULY 13, 1878

EXPERIMENT FOR ILLUSTRATING THE TERRESTRIAL ELECTRICAL CURRENTS.—The following experiment enables a lecturer to exhibit to a large audience in a very simple way the action of the currents of electricity that pass around the earth. A rectangular frame, made of light poplar wood, of section three by two centimetres, with sides in length a fraction over a metre, and in breadth three-fourths of a metre. About the perimeter of this rectangular frame twenty coils of insulated copper wire, each extremity of the wire terminating near the centre of one of the shorter sides, and passing through the wooden frame, is fastened and cut off about three centimetres from the frame. This rectangular frame is then so suspended in a horizontal position, by wires attached to the frame of an ordinary hydrostatic balance, that the longer sides are at right angles with the beam. By adjusting weights in the pans the index of the balance can be brought to the zero point. Two small orifices bored in a block of wood a centimetre apart serve as mercury cups, in which the extremities of the short terminal wires are immersed. Near the bottom and through the walls of these wooden cups are screwed small brass hooks, which serve as connections, to which the wires of the battery are attached. The balance is now so placed that the longer sides of the suspended rectangle are at *right angles with the magnetic meridian*, or in the *magnetic* east and west line. When the current from the battery is made to pass around the rectangle from east to west on the northern side, and from west to east on the southern side, by the theory of terrestrial magnetism, the northern side of the rectangle would be attracted and the southern side repelled; and that this is so the corresponding deflection of the balance renders plainly visible. When the current is reversed the deflection is in the opposite direction. By breaking and closing the circuit at proper intervals to augment the oscillations the large frame is readily made to oscillate through an arc of five degrees. When the sides of the rectangle are placed north-east and south-west the current produces no sensible effect. A bichromate-of-potash battery of sixteen cells, with plates of zinc and carbon twenty-five by six centimetres, is used. With a rectangle containing a large number of coils of wire attached to a very delicate balance, by using a *constantly-acting* battery the variation in the magnetism of the earth might be advantageously observed.

[33728.]—**Thunder and Lightning.**—Remember that for every five seconds between flash and thunder the flash is one mile distant. This you will find quite as accurate as any measurement you can get. You may either read the seconds off a watch dial, or count them, the latter preferred when you have learned how to count accurately. The velocity of sound roundly is 1,120ft. per second; hence, in five seconds the sound should travel 5,600ft., or 1,866yds. This is 106yds. beyond a mile, but the difference is inappreciable, for the distance over which every flash travels is so great that it is impossible to get an accurate distance.—W. J. LANCASTER.

THE RECENT THUNDERSTORMS.—An unusual number of accidents by lighting, both serious and curious, have been reported. At Witham the lightning ran along the telegraph wires into the instruments at the Post Office, fusing the coil of the galvanometer, shooting from thence to the testing box, with a vivid blue flame, succeeded by a loud report, and passing out and along the wires to the Braintree Post Office, seven miles distant, where some slight damage was also done.

LIGHTNING AND LIGHTNING CONDUCTORS.

[14813.]—I CANNOT agree with "J. T. M." (14814) either that the motion of a flash of lightning is so perceptible to the eye, or that every flash will have a visible ascending and descending portion. I think he can hardly argue from what is observed at the terminals of a wire circuit during the quiet passage of the galvanic current to the state of things at the moment of the eruptive discharge of lightning. In a perfect conductor the passage would no doubt be practically instantaneous; but as air is by no means a good conductor, it is not surprising that an ordinary lightning flash should be progressive, as the experience of ninety-nine persons in every hundred tells them that it is.

A downward and an upward lightning flash take place under different circumstances. The up-stroke, or back-stroke, as it is sometimes called, is simply the restoration of equilibrium at one end of a body of charged cloud travelling near the earth at the same instant that a down-stroke has occurred at the opposite end.

The result of my own experience on this point is that, when an electric discharge from the clouds strikes an oak tree, for instance, a considerable portion of the charge is dissipated in air, and it barks and splinters one, or, at most, two branches, then proceeds downwards under the bark of the stem, dividing sometimes into two or more streams, cutting grooves an inch or two deep in the timber, and then going to earth, and that is the extent of the injury. But the discharge of the up-stroke is very different, of much rarer occurrence, and far more destructive. The whole charge passes at once from the earth into the tree, and the stem or bole is completely shattered, every particle of sap being converted into steam. On reaching the junction of the branches more resistance still is encountered, and every branch is flung down or left hanging by the bark, most of them being shattered into mere splinters as the charge is dissipated into the atmosphere. Such instances are rather rare. I had the good fortune to witness one about seventeen years ago, and photographed the remains of the tree, and one has just occurred, similar in all respects, in this neighbourhood (Hereford) on the night of the 7th instant.

As some questions have been asked lately about lightning conductors, I may say that my own plan has invariably been to use 4in. strips of galvanised iron plate, riveted together, as being the safest and the cheapest. Much of the copper-wire rope I have seen used for conductors is too small to carry a heavy discharge of lightning. I have heard on several occasions of such conductors being fused, as, for instance, one at Stonyhurst College a few years ago. The iron band is easily fixed, can be diverted from the straight line at any angle, and if properly terminated above and below, such a conductor will carry off the heaviest discharge in perfect safety. Moreover, it improves as a conductor with every discharge that passes through it, whereas I believe that copper wire becomes more and more brittle.

H. C. Key.

ASCENDING LIGHTNING.

[14814.]—There seems to be a good deal of interest taken in this rather insignificant matter, and a good deal of confusion of thought into the bargain. It is quite certain that if lightning has any motion of translation at all, and is not, in fact, omnipresent in its track, it must often ascend. If the electric action is single, and passes as a current or "bolt" from the positive charged surface to the negative, it must travel both ways, because it is well known that the clouds have negative as well as positive charges. Indeed, it is probable that both always co-exist, and form a complete circuit; the visible discharge may, therefore, happen in either path, and be accompanied with what is called the "return stroke" by some, at perhaps a great dis-

ASCENDING LIGHTNING.

[14738.]—In the first paragraph of his letter
(14451) your able correspondent, "A Fellow of the
Astronomical Society," states that during a thu
storm in the neighbourhood of Tonbridge We
"very distinctly saw one flash of lightning t
upwards from the earth into a dark lowering
poised at some distance above it," and he re
that "theoretically, of course, this is a pheno
which not unfrequently occurs."

I once saw a similar phenomenon when at
with a friend during a thunderstorm at an
window of his house in the country. A vivi
appeared to shoot upwards a few hundred y
front, from the very part of a meadow at
was looking, and was instantly followed b
mendous clap of thunder. My companion
had distinctly seen the flash, but did not not
thing unusual about it, except that it was
and nearly vertical. He was, however, not
at the meadow, but at a wood on the hill
The difference of our impressions seemed
accountable.

Since that time the subject has occasio
copied my thoughts, and I am now of opi
ascending lightning is a mere illusion,
entirely to the eyes of the observer happe
directed to that part of the landscape at
discharge occurs, and that it is no proof o
having been charged positively.

letters of "F.R.A.S."

LIGHTNING CONDUCTORS.

This paper, Mr. R. Anderson's, F.C.S., was as follows:—One hundred and twenty-six years have elapsed since Benjamin Franklin discovered, by means of his famous kite, that lightning could be drawn from the clouds, and its destructive qualities extinguished by very simple means; and one hundred and ten years are gone by since the first of Franklin's "lightning rods" was set up for protection over the dome of England's metropolitan cathedral, St. Paul's. Yet, so slow has been the "march of progress" in the application of one of the greatest scientific discoveries of modern times to the uses of daily life, that even now, after the lapse of more than a century, the employment of lightning conductors, simple as they are, and as inexpensive as simple, is far from being general, still less universal. At least one-half, and perhaps two-thirds, of all the public buildings, including the churches and chapels, of Great Britain and Ireland are without protection against lightning. As to private houses, it is safe to assert that not five out of every hundred have lightning conductors. It is well-known that the amount of property destroyed annually by lightning is very great, though it is naturally impossible to form any estimate of it. However, there are some facts as to the annual destruction of human life. According to the Thirty-ninth Report of the Registrar-General, issued in July, 1878, and former reports, the number of deaths from lightning in England and Wales was 182 from 1869 to 1876. In Prussia, where the registration of the causes of death is under the enforcement of strict legal enactments, and, in consequence, far more accurate than in England, there were 819 persons reported as killed by lightning in the eight years from 1869 to 1876. The population of Prussia is larger than that of England and Wales—25¾ millions against 24¼ millions—but, on the other hand, thunderstorms are less frequent there than with us. Altogether it will be rather under than over the mark to say that as many persons are killed by lightning in England as in Prussia, the loss of life amounting to over a hundred every year on the average. The terrible losses, both of property and human lives, still occasioned by lightning are the more lamentable as they are in nearly all cases the result of the grossest negligence. The negligence is threefold, namely—first, in not providing any lightning conductors at all; secondly, in not placing them in the right position, or in sufficient number to cover a given area; and, thirdly, in not having them regularly tested so as to ascertain their constant efficiency. Of course, the first-mentioned cause of neglect is by far the most important. It is one alike astonishing and baffling all search for a reasonable explanation. Every year brings its regular thunderstorms, more or less in number, and most of them accompanied by fatalities. All see the terrible lightning flashing over their heads, all tremble before the approach of the awe-inspiring electric force, the mere touch of which brings instantaneous death, and yet but an excessively small number of persons make any efforts to protect themselves, their families, and houses against the electric fire from the clouds. Public buildings fare very little better than private houses. Even some of the first cathedrals in England, such as Peterborough, have no lightning-conductors whatever, while others, supplied with them, are insufficiently protected, as apparent to any competent observer. A glaring case of absence of protection against lightning is to be found at Windsor Castle, grandest of all the historic buildings of England, and the residence of our sovereign. It may seem incredible but I can vouch for it as an actual fact, ascertained by myself on a quite recent visit, that several portions of the noble pile, among them St. George's Chapel, home of the illustrious Order of the Garter, and the adjoining belfry tower, overhanging the main street of Windsor town, are entirely unprovided with lightning conductors. On other parts of the castle a few conductors are placed, but clearly not enough. It is needless to say that, speaking only of St. George's Chapel and the belfry tower, these splendid ancient structures, in their exposed situation, constantly touched by the storm-clouds that sweep up the valley of the Thames, are liable any moment to destruction, with irreparable loss to the nation. I now come to the third cause of neglect, which, though ranged as the last, is by no means the least. My argument is that lightning conductors ought to be at regular intervals, at least once a year, carefully inspected, and their efficiency tested by a galvanometer. The absolute neglect of this precaution, which is now prevailing, is, I believe, the cause of a vast number of casualties by lightning, inflicted upon buildings nominally protected by conductors. Exposed as they are to all the destructive influences of wind and weather, and the often still more pernicious assaults of ignorant workmen, masons, bricklayers, and others, who, while undertaking repairs, tear down ruthlessly, as a nuisance, the wonderful yet fragile string of metal which leads the electric flame on its path, it but too frequently happens that persons who have had the wisdom to erect lightning conductors over their houses, and believe themselves fully protected, are in reality far worse off than being without a conductor. But utter neglect of the conductor, when once it has been put in its place, is the commonest thing, and indeed the rule, as regards private dwellings; and, I fear, there is little difference in this respect as to most public buildings, churches, and chapels. In fact, it is the old case of a matter, however consequential, yet being utterly disregarded as "nobody's business." Other repairs to all sorts of public buildings are regularly executed; the walls are kept safe; painting and whitewash are renovated from time to time; the roof is preserved watertight; and the turret clock, if there is any, is thoughtfully looked after, oiled, cleaned and repaired. But who is there that ever inspects the half-hidden little thing on which the safety of the whole fabric against the destructive effects of lightning depends? I made a great many inquiries on this highly important subject, and the more I did, the more I was surprised at the profound negligence generally prevailing about it. Between three and four thousand pounds were spent in protecting the Houses of Parliament by lightning conductors at the time of their erection some twenty years ago. Since that time, as far as I can learn, after minute investigation, they have never been tested, and there is no guarantee whatever that a discharge of lightning may not at any time fall upon the Queen's throne, the Lord Chancellor's woolsack, or the Speaker's chair. As regards Windsor Castle, already referred to, the case is even worse. While parts of it are entirely unprotected, it is excessively doubtful whether the few conductors placed upon some of the eminences of the vast range of buildings are at all efficient, and not merely a "delusion and a snare." It is well known that the all-important matter in respect to a lightning conductor and the principal element of its efficiency is the earth connection, that is, the immediate and complete dispersion of the electric force after it has made its way from the clouds through its metal path in the ground below. Moist earth is indispensable for the purpose, and I am very sceptical as to whether the few rods that stand over the Queen's private apartments at Windsor Castle and the culminating mass of brickwork, the Round Tower, actually have their root in moist earth. If not, it would be better certainly the things were taken away altogether, and the whole magnificent structure treated like St. George's Chapel and the Belfry Tower. A French writer pithily expresses the results that follow from a lightning conductor over a house not having a proper "earth connection," by saying it is lightning guided to the owner's iron bedstead. Having drawn attention to the chief causes of the numerous and fatal casualties caused every year by lightning, I have only to add a few words of advice as to how they might be prevented, or at least greatly diminished. First of all, I think it most desirable that public recommendation should be made, by local and other authorities, to place lightning conductors on all exposed or high-lying buildings, whether public or private, as well as on those standing near woods and on moist ground. It might be well worth the trifling expense to place simple conductors also against trees and parks, under which there are benches, or where persons are likely to gather during a thunderstorm, they forming a prolific source of fatal accidents. Above all, no church, chapel, school, prison, or other large public building ought to be without one or more lightning conductors. There can be no excuse whatever for omitting this simple protective means against death and destruction, which may come at any moment, in the cases of edifices devoted to public or national uses. But if it is necessary to greatly multiply lightning conductors, it is equally so that they should be planned and erected by competent persons, with scientific as well as practical knowledge of the work. There are a hundred circumstances which ought to be taken into account in selecting the best positions for conductors, especially on large buildings and those of irregular construction; and only great experience, as well as cognition of all that we know about the movements of the electric force, can accomplish it. Of first importance are the considerations of the general design of the building that is to be protected; the soil on which it stands, whether dry or moist; the presence of masses of metal in or near the roof or the walls, as in the case before mentioned; the position of the chimneys; and similar matters affecting the course of the electric discharge of the clouds. It would be quite impossible to lay down absolute rules on the subject; still protection against lightning may be effected with the greatest certainty, under the guidance of well-known facts and observations which throw light upon the undeviating path of the mysterious electric force. But if everything possible has been accomplished towards the erection of the most perfect lightning conductor, there still remains something to be done. It is not only to construct a faultless conductor, but to maintain it always in good condition. This is a matter which, sadly neglected, and overlooked to a quite astounding degree, cannot be too much insisted upon. It ought to be universally known that a lightning conductor is worth nothing unless it is periodically tested. The testing should take place at regular intervals, perhaps best in the spring, before the advent of the summer thunderstorms, and it should likewise be made whenever a building has been undergoing repairs which may have damaged the conductor. To show the importance of constantly testing even the best laid conductors, I can cite another instructive case where a house was apparently well protected. On the 19th of August, 1876, shortly before midnight, a heavy stroke of lightning fell upon the mansion of Mr. Evans, civil engineer, Claypounds, near Kew Bridge, Middlesex. The electric force destroyed the top of a large chimney, knocking off part of the coping, not more than 2 or 3 feet from a lightning conductor, to which it then flew, making its way down to the earth, but not without causing the greatest disturbance all along its path, lifting up, among others, some heavy marble toilet tables in bedrooms some 6 feet distant on either side from the copper rope, which, under ordinary circumstances, would have carried the electric force noiselessly, as well as harmlessly, to the ground. The fact of this disturbance indicated at once the source of mischief. The lightning conductor, good as it otherwise was, had no sufficient earth-connection. It went into the earth, it is true, but into soil altogether dry, and therefore the conductor did not, and could not, act properly. It thus came to pass that, first of all, the lightning did not touch, as it would otherwise have done, the conductor directly, but sprang upon the coping of the neighbouring wall; and that, although it made its way down into the earth afterwards, it did so, as it were, with the greatest effort, which caused the lifting up of the marble tables and other disturbances.

PROTECTION AGAINST LIGHTNING.

This year has been remarkable, on both sides of the Atlantic, for the number and severity of its thunder storms. The neighbourhood of London has especially suffered. Looking back on the summer, it seems to us as if every Sunday had brought an impressive sermon of this kind, which, if it taught no other lesson, was at least a warning to those Sabbath breakers who, in their best clothes, had exposed themselves on Hampstead Heath or Clapham Common. Now, that, after such an oppressive August, we breathe freely, attention may be appropriately called to a paper read by Mr. Anderson to the British Association, on accidents by lightning and the means of guarding against them.

Mr. Anderson's statements are by no means assuring. Many of us, when caught in a thunderstorm, have been accustomed to take refuge, first, it may be hoped, in a good conscience, and then in statistics, which, without ever having looked very closely into them, we felt sure would be in our favour. When the bolts were flashing around, we have kept telling ourselves that, if the truth were known, we were, after all, safer than in crossing Regent Circus on a busy afternoon, or in travelling by express train from Holborn to Ramsgate. But Mr. Anderson informs us that, from 1869 to 1876, the deaths from lightning in England and Wales are recorded as 182; and this estimate he takes to be very much under the mark, sin[ce] during the same period, 819 deaths from lightning a[re re]ported in Prussia, where, with a population very slight[ly] larger, there are fewer thunderstorms and a more complet[e] system of registration. Surely, he must be mistaken in hi[s] supposition that over a hundred people are killed every yea[r] by lightning in this country. In America the ordinary number is from fifteen to twenty, if we may rely upon an electrical contemporary. We should be glad to receive further information on this point. Such information ought to be attainable, and would certainly be useful in teaching sensible people what they really had to fear from thunderstorms, though no amount of statistics would lessen the dread with which ignorant and nervous people behold these manifestations of the powers of nature. In the meanwhile, we are inclined to think that, in our climate, fewer lives are lost by the stroke of lightning than by being wet through in a storm, and that the danger to property, year by year, is not so great as that arising from the more frequent and less terrific phenomenon of a child playing with matches. So, if any of our readers should be unavoidably exposed to the rage of the elements, we advise them to keep a good heart, to think of the drains, the Corporation dinners, the metropolitan water companies, and all the more fatal weapons of death through which we are daily and hourly running the gauntlet, and, above all, not to place their bodies in any position likely to become the line of least resistance for the electric discharge.

Though we cannot accept Mr. Anderson's estimate of accidents from lightning, we are at one with him when he dwells on the want of reasonable precaution which is just in proportion to our unreasonable dread. Forty years after Franklin's celebrated discovery, his biographer observed with surprise how backward we in England were to avail ourselves of it; and now Mr. Anderson brings forward facts to show what astonishing carelessness, to give it no worse name, still prevails among us about the proper use of lightning conductors. Not only are a very small proportion of private houses provided with them, but he tells us this simple precaution is not applied to at least one-half, and probably two-thirds of our public buildings, including some of those magnificent cathedrals whose loss would be irreparable. Windsor Castle itself, he declares, from his own observation, to be insufficiently protected. It cannot be too widely known that a lightning rod is not to be relied upon as protecting more than an area extending twice its own height. At Windsor Mr. Anderson, on a recent visit, found no conductor on St. George's Chapel, or on the adjoining belfry tower; while, as for the rods that stand over the Queen's private apartments, he is very sceptical as to whether they "actually have their root in moist earth." Here is another danger of which the general public is almost entirely unaware. A man puts up a lightning rod, and for the rest of his lifetime fancies himself safe beneath its slender shadow, though, for many years, it may not have been tested, and may have originally been erected without any scientific knowledge being called into counsel. But, unless his conductor is complete, with a good connection with perfect earth, it may be actually worse than useless, since it only acts by becoming part of the cloud, so to speak, and gives off lateral charges during the impeded passage of the electricity, with results that may be imagined, and are described by Mr. Anderson in one instance as "lifting up heavy marble toilet tables in bed rooms some six feet distant on either side of the copper rope, which, under other circumstances, would have carried the electric force noiselessly as well as harmlessly to the ground."

Such a danger could have been foreseen by a scientific electrician; but it is to be feared that many lightning-conductors are no more efficient. Suppose that a conductor ends in dry shallow earth, embedded in chalk, it is only inviting the lightning to pass with difficulty and disturbance along the premises thus insecurely guarded. Good earth, in the electrician's sense, is not to be had so easily as that which a gardener would approve of. It is always safe if your conductor leads into a stream or well, where the electricity will be at once conducted away. If this be out of the question, it is well to bury a few sacks of coke in moist earth, and let the end of the rod terminate among the coke, rivetted to a large fragment of gas carbon or graphite, carefully providing against oxidisation by insulating the rivetted joint, preferably with paraffin wax; this contact will last a century. To make sure, the conductor may be tested with a galvanometer connected with "dead" earth elsewhere; if, then, the resistance be found to be merely the resistance of the wire, you may consider you have a real protector so long as the apparatus remains intact.

All owners of property should follow Mr. Anderson's strong recommendation, that competent persons be employed not only to erect but periodically to test lightning conductors at every point where they may be required. In Paris, he says, and other French towns, there exists a regular system of inspection and testing. Those who have the charge of our public buildings should lose no time in looking to this matter. The season of thunderstorms is not yet over, and as things stand now, the Bishop of Peterborough, sitting on his episcopal throne, may any Sunday become the vehicle of an electrical discharge, struggling like a giant to reach its native earth by way of the verger's mace. We wish his lordship no harm; yet we cannot but recall Sydney Smith's celebrated dictum on the most effectual way of calling attention to a neglected danger.

THE ELECTRICIAN, SEPTEMBER 7, 1878.

55

ASCENDING LIGHTNING.

[14738.]—In the first paragraph of his letter [14631] your able correspondent, "A Fellow of the Astronomical Society," states that during a thunderstorm in the neighbourhood of Tunbridge Wells he "very distinctly saw one flash of lightning strike upwards from the earth into a dark lowering cloud poised at some distance above it," and he remarks that "theoretically, of course, this is a phenomenon which not unfrequently occurs."

I once saw a similar phenomenon when standing with a friend during a thunderstorm at an upper window of his house in the country. A vivid flash appeared to shoot upwards a few hundred yards in front, from the very part of a meadow at which I was looking, and was instantly followed by a tremendous clap of thunder. My companion said he had distinctly seen the flash, but did not notice anything unusual about it, except that it was straight and nearly vertical. He was, however, not looking at the meadow, but at a wood on the hill beyond. The difference of our impressions seemed to us unaccountable.

Since that time the subject has occasionally occupied my thoughts, and I am now of opinion that ascending lightning is a mere illusion, and due entirely to the eye of the observer happening to be directed to that part of the landscape at which the discharge occurs, and that it is no proof of the earth having been charged positively.

Wheatstone proved that the duration of the electric spark is about 1-24000 of a second, and he also showed by means of a revolving wheel, that the duration of the lightning flash is little more, and cannot exceed a minute fraction of the thousandth part of a second. The moment of time it continues visible to the eye—about the tenth of a second—is therefore hundreds of times greater than its actual duration. Now, is it credible that we can judge by the eye of the direction of motion in a case like this—that we can see the progress of the end of a flash of lightning?

The idea seems absurd, yet this feat must be performed before we can know with certainty whether a flash has travelled in this or that direction.

The following simple experiment will serve to illustrate the argument:—Place before the ball of the prime conductor of a good electrical machine another ball of equal size connected with a discharging train, and so adjust their distance apart that on steadily working the machine distinct zigzag sparks shall pass across the interval. Now, let several persons attentively watch the balls, and say from which of them each spark proceeds. Opinions are pretty sure to differ, but the following rule will be found to have no exceptions:—*The spark appears distinctly to issue from that ball to which the attention of the observer is directed.* It is worthy of note that the end of the spark next the negative ball is the brighter and thicker.

Let me, in conclusion, acknowledge the pleasure and instruction I have derived from the excellent letters of "F. R. A. S." J. T. M.

Powder Magazines without Proper Lightning Conductors.

Oct/78

We have to record the explosion of 1,200 kegs of giant powder at Pottsville, Pa., ignited by a stroke of lightning, and which spread death, ruin and devastation all around.

Public safety demands that the authorities appoint competent inspectors to determine whether a locality where such dangerous material is stored can be considered safe, or can be made safe by the proper and well-known precautions. It is dangerous to trust to the owners of the material or their employés, of whom often the one is as ignorant as the other, and do not know what reliable guarantees science has provided against such calamities.

In mentioning the reliable guarantees, we do not mean the flimsy lightning-rods stuck up all over the country and improperly connected with the ground. Many of them are not worth anything, offer no protection whatsoever, and are the cause of the loss of confidence of many in protection by lightning-rods.

A powder magazine should have no lightning-rods at all, as they are apt to attract lightning; it should for the same reason not be situated on an eminence, but in a valley, and all the metallic parts of the roof be connected by means of a number of iron rods placed in different parts around the building and passing into moist ground below, the rods being carried in the earth for a distance of several rods from the building and there connected with vertical rods driven in the ground deep enough to reach moisture; if the ground is rocky, they should be carried into neighboring streams, wells or creeks where the most moist portions of the neighborhood are reached.

Then for additional security, four or five poles of the size of ordinary liberty poles should be erected around the building at a distance of say 50 feet, each carrying a pointed lightning-rod on top, with a metallic connection united with the moist ground underneath. Such elevated rods would silently discharge most of the electricity accumulated in the clouds, and in case of a violent discharge in mass would receive all the damage and make a discharge through the powder magazine itself impossible.

The reports do not state that the magazine referred to above was provided with any safety contrivance against lightning. If so, it is evident that it was of the kind we have so often seen—a vertical rod on the highest part, and a bar of iron running down from it along the wall and stuck the distance of a few inches into the dry ground below. Such a lightning-rod is worse than useless, as the principal thing is lacking, which is a perfect ground connection. We have always insisted on the right understanding of the fact that the truly protective part of a lightning-rod is not that on the top of the building, but below in the ground. When the ground connection is imperfect the lightning will not go there, but may pass through the house, always following the path of least resistance, and it appears that in the case described the path led straight through the middle of the giant powder.

56

LIGHTNING CONDUCTORS.

[14054.]—I ask permission to describe a very simple and inexpensive mode of protecting buildings against the heavy discharges of atmospheric electricity with which we have all become recently so painfully familiar. It consists in utilising the iron or other metallic rain-water pipes of our houses by bringing them into free electric communication with the roofs by means of gas-coke, which is known to be an excellent conductor of electricity. For this purpose, let a line or row of blocks, or pieces of coke, of moderate size—though the larger the surface presented by them the better—be placed in close apposition across the roof of the house or building, and just beneath the chimney or chimneys (a row of similar blocks might also with advantage be raised upon these against the side of the chimney-stack as high as, or even higher than the latter); and after fixing the blocks, by cementing the under surface of each, let them be carried along the roof to the gutter, so as to bring them into as direct connection as possible with the upper end of the rain-water pipe, and thus to form a continuous electric conductor; and for greater safety a line of smaller blocks, in contact at one end with those under the chimney, might be carried also along the ridge of the roof. The other end of the water-pipe, if not passing directly into the sewer of the house, must be brought into free and uninterrupted communication with the earth, by connecting it with small blocks or pieces of coke buried at some depth beneath the surface. And to realise this all-important object—namely, the rapid and complete transmission of the electricity to the earth—it may be proper to mention that in the case of the ordinary iron and copper lightning conductors, "three bushels of coke, broken up into small pieces, and packed round the bottom of the rod, are found, according to the French engineers, to secure a quarter of an acre of moist contact with the earth, in consequence of the number of pores contained in this substance." A hole then filled with a like quantity of broken coke, or about three bushels, would, I conceive, form an ample channel of escape for any lightning discharge that might fall upon a house, upon the plan that I have ventured to suggest. It is almost unnecessary to add that the rougher the blocks or pieces of coke selected for the above purpose the better, on account of the greater number of collecting points for the electricity which they present.

W. H. O.

Atmospheric Electricity.—In a recent memoir read before the Academy of Naples, Prof. Palmieri gives the results of his 27 years experience of this subject. He is of opinion that the formation of aqueous meteors and clouds is always attended by the liberation of positive electricity; but these clouds can afterwards change themselves negatively by induction. When negative electrification is observed, it is due to perturbations resulting from discharges at distances more or less great. In dry clear air where the distribution of positive electricity is normal, the potential diminishes with increasing height, a result different to that obtained by other observers. Nov 78

Nov 78

Compound Lightning.—Mr. E. H. Pringle, in a letter to *Nature*, October 3rd, states that "compound lightning flashes," or discharges, where several flashes follow each other rapidly in the same track, are to be seen in almost every tropical thunderstorm. When the flashes succeed each other quick enough, the effect is "beaded lightning." It is singular that the electricity should collect so rapidly; for the after-flashes do not seem to be merely residual.

as often as required. The induced currents are obtained from the screws numbered 5 and 6; the extra current passes between 6 and 7; whilst both combined are obtained from 5 and 7.

The second form of regulator, for ordinary medical use, was recently presented to the Académie de Médecine by M Gararet. Its indicating needle and graduated limb are drawn in K and L (fig. 4). It may be briefly described as a vibrating armature of special construction, involving the principle of the pendulum, so that, by the movement of K, the number of its oscillations per second may be varied between tolerably wide limits. The figures marked upon the limb *l* are determined in each case by a simple experimental method involving a small chronograph and registering apparatus specially constructed for the purpose.

The reversible battery cell, represented in Fig. 5, has been

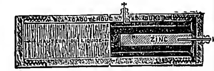

Fig. 5.

described in these columns on a previous occasion. When the fluid, a solution of bisulphate of mercury, occupies the position shown in the cut, the couple formed by the elements in the upper portion of the cell is not brought into action, and there is no consumption of material; but, when the cell is placed on its side or reversed, the couple is immediately rendered active.

ATMOSPHERIC ELECTRICITY.*

By Professor Palmieri.

Putting aside certain temporary apparatus designed to prove the existence of atmospheric electricity, such as the kite, captive balloons, the bow and arrow, and other similar contrivances, it may be said that for the daily observations of meteorology there have been used, in the first place, fixed conductors terminating in a point or "flame," next the moveable electrometer (Peltier), and, lastly, the fixed electrometer with moveable conductor (Palmieri and Thomson). The method of fixed conductors was triumphantly combated by Peltier, and I myself, without repeating what was demonstrated by the French physicist, showed further how, with that method, the observer might be deceived not merely as to the quantity, but also as to the quality of the induced electricity.†

Peltier's method, by use of the moveable electrometer, was undoubtedly a step in advance, but few were able to appreciate it; and, although Wheatstone recommended it to the British Association as the only one capable of giving results of any value, it attracted but little attention.

In 1850 I applied myself to the study of atmospheric electricity. I observed that, although Peltier's method was an important gain to electrical meteorology, nevertheless, it was not exempt from certain defects, owing to which it was impossible to get observations exact enough for comparison, and I endeavoured to find, therefore, some better method, as well as a thoroughly exact electrometer.

As regards the method, I studied the electrical manifestations occurring in the open air when two conductors are brought near to, or separated from, each other horizontally. I found that the tensions, which are manifested through contiguity, are of an opposite, whilst those which are obtained by separation are of the same nature as the electricity prevalent in the atmosphere. So that, in normal times, two conductors that are brought near to each other show negative electricity, but positive if they are separated. This law is, of course, inverted when negative electricity prevails in the atmosphere. The electrical tensions which we get in this way follow, as to their intensity, that of the air. These are the only facts which prove the electricity of bodies placed on the earth, or, if you will, the electricity of the earth; but, at the same time, they show that that electricity is induced from that of the air, and is not proper to them. If, then, this electricity of the earth is always opposed to that of the air, and follows exactly the phases of increase and diminution of the latter, it is clear that the former is induced electricity, and not *sui generis*, and thus one can understand the fact—often noticed by me—that, whilst at the University Observatory, the earth shows negative electricity to a very strong degree when two conductors are brought near to each other in the open air, at the Observatory of Vesuvius at the same time we get positive electricity—I say at the same time, for the observations were compared by telegraph. The electricity that is manifested at the approach or separation of two horizontal bodies being, then, exactly proportionate to that of the atmosphere, I concluded that from the former one might get the measure of the latter, since, to whatever method we have recourse, that which is measured is the force of the influence exerted on thoroughly exposed conductors by the electricity of the atmosphere. For reasons which it is not necessary here to repeat, I did not confine myself to the method of horizontal approach and withdrawal.

By the aid of water, I set about the study of the electrical phenomena of ascending and descending streams, and determined the origin of those electrical manifestations noticed by Tralles and Volta as occurring with the spray of the cascade.

With the descending jet I found, amongst other things, that when the vessel is insulated electricity homologous to that of the atmosphere manifests itself during the flow of the water. The same phenomenon occurs with other liquids, and also with pellets of lead, metal filings, and even with the ashes of Vesuvius.

(TO BE CONTINUED.)

* Translated from the *Elettricista*.

† I need scarcely repeat what has already been remarked by Peltier and so often verified by myself, namely, that the fixed conductors often remain for whole weeks perfectly mute, on account of electric dispersion. Volta observed that a fixed conductor required 5' to attain the maximum of its charge; and this is in conformity with the known laws, since to become charged through the point takes time, and in this period, relatively a long one, losses will have occurred which, owing to their extent and variability, it would be impossible to calculate. Thus, frequently the whole is dissipated, as happens not seldom even to the conductor of an electric machine. What means then can be employed with fixed conductors? First, in regard to the deceptions which they occasion, I do not think that they can be avoided by use of the method proposed by Volpicelli, because even on calm days, whether owing to currents in the upper regions of the atmosphere, or to other causes not yet determined, there occur sudden and rapid changes through which the curve made with observations, taken at short intervals, nearly always turns out angular (see my "Lectures on Terrestrial Physics"). The fixed conductor, then, in a time of positive electricity will give negative electricity simply by a diminution of the inductive energy in the atmosphere, and this not only in stormy weather, but even when it is fine. This is why many times it has happened to me to get negative electricity with a fixed conductor, and positive with a moveable conductor. During the eruption of Mount Vesuvius in 1872, whilst the needle inclined itself towards the Observatory, the fixed conductor frequently signalled negative phases, the moveable conductor showing instantly a positive current.

THE SOCIETY OF TELEGRAPH-ENGINEERS.—CABLE

The opening meeting of the present session of the above Society was held on Wednesday evening, the 13th of November, in the hall of the Institute of Civil Engineers, Great George-street, Westminster. The chair was occupied by Mr. W. H. Preece, vice-president.

Mr. Andrew Jamieson, C.E., was called on to read his paper on "Cable Grappling and Cable Lifting." The author remarked that, before entering on the main subject of the paper, it would be as well to briefly analyse the chief causes of the interruption and breakages to submarine cables. The chief causes might be enumerated as follow:—First, total breakage, due to abrasion, suspension between submarine eminences, insufficiency of slack, volcanic eruptions, or terrestrial disturbances, or possibly large masses of rock becoming detached and falling across the cable in their descent; second, in shallow water the cable was often broken from ships' anchors; third, faults were caused by teredos or other marine animals boring; fourth, break of the conductor, with perfect or good insulation; fifth, latent faults in the cable when laid, developing afterwards, or deterioration of the core, joints, or sheathing, and, sixth, and last, lightning. Reviewing the six causes, they came first to breakages due to abrasion. This cause was mainly attributable to the cable being swayed to and fro under the influence of tides, currents, &c., and the only means of guarding against them was to submerge the cable very carefully, and use as heavy a type of cable as possible. The floating in suspension was clearly due to insufficiency of slack, and hence the great importance of a thorough knowledge of the ground over which the cable was to be laid. Volcanic eruptions or terrestrial disturbances were actions over which we have no control, and for which at present no visible means of provision could be made, except that of using as heavy a type of cable as possible where they were to be apprehended. As to breaks by ships' anchors, this danger could only be lessened by using as heavy a type of sheathing as possible, and carefully marking off the ground by buoys or otherwise, and as far as possible avoiding anchorages. The frequent injury to the core by teredos or other marine animals might be guarded against by coating the core and servings with some anti-teredo substance, which would be either distasteful or fatal to the animal, and have no effect on the cable. Various means had been proposed with this object in view. The causes of interruption from a broken conductor, with perfect or good insulation of the core, were due to an over straining of the copper wire in the manufacture, or in paying out, or, perhaps, to the brittleness of the copper. The simple remedy for this kind of fault was taking great caution to have the core of the conductor thoroughly annealed, and capable of bearing a certain strain with elongation before breaking, and being careful not to put more strain on the same when twisting it into a conductor than was absolutely necessary to form a good lay. As regarded provision against latent faults in the cable when laid, or deterioration of the core, or joints, or sheathing, they must look for a remedy in a thorough system of electrical testing. With regard to interruptions caused

Éclairs observés au Brésil

Nous trouvons sous ce titre, dans la *Nature* de Paris, un très-curieux article de M. Léon Dumas sur la forme des *éclairs observés au Brésil.*

Il nous a été donné d'observer, en août 1877, lors d'un orage assez violent qui avait pour théâtre la petite ville de Vanouras, dans la province de Rio-de-Janeiro, deux formes singulières d'éclairs. Les décharges électriques se suivaient sans interruption et affectaient pour la plupart le trait sillonné, d'observation commune.

Mais dans les zones intertropicales, la tension électrique des nuées est plus forte que chez nous, par suite de l'[illegible] des phénomènes d'évaporation ; de là, des dessins parfois bizarres occasionnés par certaines ramifications des éclairs.

Une forme d'éclair fort curieuse est figurée dans le premier de nos croquis (fig. 1). C'est une sorte d'explosion offrant, dans ses contours, quelque analogie avec la flamme d'une bougie. La décharge affectait, au lieu du zigzag habituel, un ensemble pyriforme allongé, rectiligne, encadré d'une auréole également fort allongée.

Une seconde forme d'éclair (fig. 2), plus commune sous la zone torride, présente un tronc principal, jaillissant d'un épais nimbus, se subdivisant en deux branches, dont l'inférieure ne tarde pas également à se subdiviser. Cette forme se rapproche assez bien des éclairs arborisés déjà signalés par M. Em. Liais.

Les phénomènes électriques, bien que communs au Brésil, n'ont pas généralement l'intensité qui rend les orages des Antilles et des Indes si redoutables. Nous attribuons ces faits à l'orographie du pays et à sa végétation. Les chaînes de montagnes sont nombreuses et n'ont pas de ces pics saillants qui semblent tout attirer. Ce sont, pour ainsi dire, autant de sommets situés à peu près à la même altitude et dont chacun exerce un rôle dans les échanges aériens.

D'autre part, la végétation couvre le pays d'un superbe manteau protecteur. Le pouvoir des pointes est exercé par des milliers d'organes qui permettent un écoulement constant de l'électricité négative du sol. Est-ce à un état réfractaire que certains végétaux doivent leur réputation d'attirer plus spécialement la foudre, en occasionnant des vides dans les zones protégées ? Nous n'en savons rien. Mais c'est là la réputation faite notamment au *Peroba* (aspidosperma Gomesianum), aussi se garde-t-on bien de l'employer comme bois de charpente.

Les nuages élevés échappant en partie à ces recombinaisons constantes, les deux manières d'être de l'électricité donnent lieu à des décharges accidentées dans leur parcours par suite du voisinage de nuées différemment électrisées. Le ton rose-violet des éclairs indique déjà une élévation fort grande.

D'observations quotidiennes, trop courtes malheureusement, nous avons pu constater que les éclairs muets ou éclairs de chaleur se manifestaient de préférence dans les régions où l'altitude était la moindre.

L'auteur paraît avoir été induit en erreur dans cette dernière assertion, car les éclairs dits de chaleur sont produits par des décharges entre les nuages, ou par les reflets d'éclairs éloignés, et par conséquent ne peuvent se produire dans le voisinage immédiat de la terre.

Quand l'étincelle électrique y pénètre, c'est toujours en se faisant accompagner de tous les effets qui rendent la foudre si terrible et si bruyante.

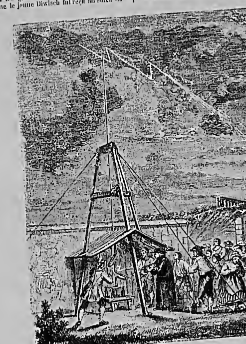
tuyant sous les bois, ou serpente au milieu des riches terroirs. C'est là que Diwisch passa la plus grande partie de sa vie et cette agréable situation a dû avoir certainement une grande influence sur les tendances et sur les études de ce jeune homme. Les violents orages qui éclatent fréquemment dans cette contrée, et principalement au prieuré de l'ordre des Chevaliers de la Croix, en face de la ville, ont pu lui procurer de fortes émotions : il a pu aussi trouver l'occasion d'étudier la foudre.

A quelques minutes de Znaïm, dans la direction du sud-est la grande route de Prague à Vienne traverse la Taïa : on voit en cet endroit les grands bâtiments d'un cloître de religieux. C'est là que le jeune Diwisch fut reçu au sortir du collége. On l'encouragea à entrer dans les ordres; en 1720 il prononça ses premiers vœux et, six ans après, il était fait prêtre.

Il devint bientôt un professeur excellent : il fut d'abord chargé d'enseigner les sciences naturelles et philosophiques. Au bout d'un an, on lui confia l'enseignement de la théologie; il contenta tellement ses supérieurs dans l'exercice de cette fonction qu'ils lui conseillèrent de passer le doctorat. Sa thèse « *Tractatus de Dei unitate sub inscriptione A et O* », soutenue à Salzbourg le 5 août 1733, lui valut le titre de docteur.

Le sort le désigna bientôt après pour la cure de Brenditz. Pendant la première guerre de Silésie, il vint administrer le



Expérience de d'Alibard à Marly, le 10 mai 1752.
Première démonstration de la présence de l'électricité dans les nuages orageux.

cloître du Pont, dont le prieur avait été mis en prison ; il s'acquitta fort bien de cette mission, et, la guerre terminée, il retourna dans sa paroisse. C'est là qu'il demeura jusqu'à sa mort.

Comme les devoirs d'un pasteur ne sont pas bien lourds dans un petit village, Diwisch put s'occuper pendant de longues années et avec un zèle admirable de nombreuses études. On sait qu'il commença ses expériences en 1727 ou 1728, et que depuis son retour à Brenditz, qui date de 1740, il s'occupa spécialement de recherches sur l'électricité.

Ayant lu dans la *Gazette de Prague* le récit de la mort du physicien russe Richmann, Diwisch publia un traité où il exposait les raisons pour lesquelles les tiges de fer employées par le professeur Richmann étaient tout à la fois sans utilité et pleines de dangers. Il terminait en décrivant un appareil capable d'attirer l'électricité atmosphérique et de la conduire sans danger dans le sol. Il fit exposer ses idées à l'Académie des sciences de Berlin par Euler, physicien distingué et mathématicien. Mais on ne prêta aucune attention à sa découverte. Un opuscule d'Euler, qui parut un peu plus tard, en 1761, et qui traite de Diwisch et de son invention, passa inaperçu.

Sûr de son fait, le prêtre de Moravie entreprit de construire lui-même son grand appareil, et, dès le 15 juin 1754, il le dressa près de son presbytère. Voici la description de ce paratonnerre dont nous reproduisons le dessin (fig. 1).

Au-dessus d'une large porte, placée verticalement, haute d'abord de 48 pieds, puis ensuite de 130, lorsque la première hauteur eut été reconnue insuffisante, s'élève une tige de fer, épaisse d'un pouce et demi, et se terminant par une pointe. Au-dessous de la pointe sont trois ailerons en tôle, mobiles sous l'action du vent et dont le seul usage est d'effaroucher les oiseaux. Du milieu de la tige principale, dont il vient d'être question, partent quatre tiges secondaires, dont chacune supporte près de son extrémité une barre horizontale. Les quatre tiges secondaires et les barres qu'elles supportent offrent en tout douze extrémités. Chacune de ces extrémités est recourbée afin de supporter une petite caisse en métal. Ces caisses (fig. 2) ont un pied de long; elles sont remplies de limaille de fer et fermées par un couvercle en bois,

60

garni de trous ; dans chacun des 27 trous d'un couvercle s'enfonce une petite broche, et cette broche qui a la grosseur d'une épingle à cheveux (fig. 3) est fixée dans le couvercle à l'aide d'une rondelle en bois qui fait pour ainsi dire office de bouchon. Toutes ces broches s'enfoncent par leur partie inférieure dans de la limaille de fer. La grosse poutre sur laquelle repose la tige principale est garnie d'armatures métalliques destinées à lui donner plus de solidité : quant à cette tige de fer, elle est reliée à la terre par des chaînes dont le double rôle est de conduire l'électricité et de servir à faire tourner la machine météo sur son pivot. Ce fut cet appareil qui fut dressé le 15 juin 1754. Voici comme Diwisch raconte ses premières expériences :

« A deux heures de l'après-midi, un orage s'éleva du Nord et se dirigea dans la direction de l'appareil : on vit des traînées blanches et déliées venir vers le paratonnerre. Quelques minutes après, on aperçut au-dessus de lui un nuage blanc; puis l'orage se dissipa, il disparut vers l'Est. Le 17 du même mois, il s'éleva de tous les points de l'horizon un nouvel orage; mais au-dessus de l'appareil les nuages restèrent blancs. (A midi, Diwisch fit descendre le paratonnerre afin de voir si le fluide avait produit quelque effet.) Aussitôt qu'il toucha le sol, les nuages blancs changèrent de couleur; ils s'obscurcirent : l'orage monta; tout le ciel devint noir; les éclairs brillèrent; le tonnerre éclata et d'instant en instant devint plus terrible. (Trois quarts d'heure

Le physicien Richmann foudroyé dans son cabinet de physique à Saint-Pétersbourg par l'électricité d'un nuage orageux, le 6 août 1753.

après, Diwisch fit replacer l'appareil sur le poteau et plaça lui-même les chaînes de fer reliant le paratonnerre au sol.) A peine était-il dressé que la foudre éclata sur lui avec un fracas terrible; les nuages se déchirèrent, et, juste au-dessus de la tige métallique, on vit une zone brillante, mesurant environ huit pouces de diamètre (?). Le ciel redevint calme à Brenditz, bien qu'on aperçût encore dans le voisinage quelques faibles éclairs et qu'on entendît encore le bruit du tonnerre. Trois minutes après, un gros nuage gris s'avança du Nord, et descendit fort bas; il vint tout près de l'appareil et se divisa : une partie alla rejoindre un nuage orageux; tous deux cessèrent de tonner au-dessus de Brenditz et ils se fondirent en une douce pluie. »

M. Mayer entre dans d'autres détails que le défaut d'espace nous empêche, à notre grand regret, de reproduire aujourd'hui.

Ainsi que le dit notre jeune et érudit correspondant, il est véritablement étonnant que l'on ait attribué à Franklin le mérite de l'expérience exécutée par d'Alibard à Marly-la-Ville.

Il y a longtemps que cette injustice nous a frappé pour la première fois, mais nous ne nous étions point arrêté à en pénétrer les causes. Nous ne l'aurions peut-être jamais fait si la nécessité de répondre à M. Mayer ne nous avait conduit à pratiquer dans les archives de l'Académie des Sciences des fouilles qui nous ont permis d'examiner des faits du plus haut intérêt.

C'est le 10 mai 1750 que fut exécutée à Marly-la-Ville, la merveilleuse observation qui eût immortalisé d'Alibard s'il eût vécu dans un pays où la routine d'intrigue et la camaraderie avaient une influence dont nous pouvons facilement nous faire

ailleurs, j'avais publié dans différents ouvrages la même analogie qu'il avait cru apercevoir entre le tonnerre et l'électricité.

« Je demande, de plus, que cet écrit soit transcrit dans les registres de l'Académie, afin que j'en puisse avoir acte au cas que j'en aie besoin. »

Ainsi, cet habile homme, par un tour de force dont les académiciens de nos jours ne sont point susceptibles, niait la réalité des expériences de d'Alibard, en même temps il prenait ses précautions dans le cas où les faits annoncés seraient réels. Alors il entendait s'en attribuer le mérite, et il déclarait par avance qu'il les avait parfaitement prévus.

Ce qui est véritablement honteux c'est que les expériences se succédèrent avec rapidité. Delor les répéta à la place de l'Estrapade, Lemonnier en donna la représentation à la campagne du duc d'Anjou, à Saint-Germain.

Mais l'Académie des Sciences tint bon et le *Mémoire de d'Alibard* NE FUT POINT INSÉRÉ.

Nous ne saurions exprimer assez énergiquement notre mépris pour les savants plats et vils qui ont donné leur assentiment à une si scandaleuse suppression.

Ils étaient les dignes prédécesseurs des plus ridicules tartufes scientifiques qui aient endossé l'habit vert, depuis que l'Académie a reçu cet uniforme.

Heureusement, M. de Buffon, qui s'intéressait à d'Alibard, lui conseilla de publier une traduction du livre dans lequel Franklin exposait ses découvertes et d'y consacrer un chapitre à la reproduction de son mémoire à l'Académie.

C'est grâce à ce subterfuge, qui n'eût pas réussi, sans la protection du comte de la Marche, qui fournit l'argent, que la gloire de d'Alibard a surnagé.

Il était étouffé par le coupable Nollet, si Franklin n'était venu à la rescousse et n'avait pris, par conséquent, dans cette affaire la part du lion.

On croyait, à cette époque, que les tiges isolées absorbaient l'électricité des nuages, et, en contact avec elles, on suspendait des masses métalliques qu'on nommait des *réservoirs d'électricité*.

Ajoutons que tous les opérateurs affichaient une sécurité aussi grande que celle du brave curé de Marly-la-Ville. Nul ne croyait qu'il fût nécessaire de prendre la moindre précaution pour se garantir contre l'écoulement du fluide accumulé dans les réservoirs d'électricité.

On ne commença à comprendre le danger que lorsque Richmann eut été foudroyé à Saint-Pétersbourg.

Sauf les dimensions, son appareil était identique à celui dont d'Alibard, Delor, Lemonnier s'étaient servis.

Jusqu'à cette époque, personne n'avait songé à mettre les réservoirs d'électricité en contact avec le réservoir commun.

Cette nouvelle phase de l'invention des paratonnerres doit maintenant être examinée.

W. DE FONVIELLE.

61

Annalen der Physik und Chemie, No. 12, 1878.—In an inaugural dissertation here given, Herr Nahrwold studies atmospheric electricity; his method of experiment having been to electrify air in a cylindrical vessel fitted with a (mercury) dropping collector. His first attempts, with points, convinced him that only the dust, not the air, could be thus electrified; he then successfully used a fine platinum wire kept glowing with a battery (the air having been first freed from dust), and a condenser or galvanic element connected with the circuit. Interesting data are furnished with regard to the charge of the air, the ratio of this to the source of electricity used, and the decrease of the charge. Some of the observations seem to throw doubt on Thomson's conclusions as to the distribution of electricity in the upper regions of the atmosphere.—Herr Wiedemann offers a theory on the nature of spectra, deduced from the kinetic theory of gases. Line-spectra are attributed to oscillatory motions of atoms, isolated at high temperatures; band spectra of elements and spectra of compounds to vibrations of atoms in the molecule, or of the ether-envelopes. —A quantitative verification of the electrodynamic law, regarding the reciprocal action of closed circuits, for the case in which the circuit suffers deformation, is furnished by Herr Niemöller.—Herr Korteweg discusses the velocity of propagation of sound in elastic tubes, and Herr Rühlmann gives formulæ for measurement of ocean depths with the manometer.—There are several notes on crystallography.

A New Telegraphic Conductor.

An electrical conductor of decidedly novel character has just been patented by Mr. Alberger, of Philadelphia. It consists of a conducting wire—preferably of decarbonized steel—surrounded by a vitreous substance and incased in a metallic tube. The manner of making the conductor is as novel as the article itself. The inventor produces a glass bulb at the end of a glass blower's tube, and passes a wire from a neighboring reel through the tube until its end reaches the outer end of the bulb, when the end of the bulb and the wire together are seized and drawn outward, while the tube remains stationary. The wire having the vitreous casing is now introduced into a wrought iron tube, and the whole is heated to a welding heat and reduced in size by rolling. Sections of the conductor are united at the ends by an ordinary screw coupling, the ends being first rounded off by an emery wheel to render a contact of the conducting wires certain. The conductor made in this way is protected from oxidation, and is completely insulated. March 77

62

Atmospheric Electricity

[T]races afforded by the self-registering electrometer at this obs[erv]atory show that the conditions of the atmospheric electricity at Kew were very similar during the recent frosts to those observed at Montsouris by M. Descroix. We have, however, in the automatic instrument the great advantage of continuous registration, and therefore our information is not limited to the results afforded by seven observations daily.

The whole period of the frost was characterised by extremely high tension which with us averaged and frequently exceeded the amount which sufficed to derange the French instrument.

The absolute maximum tension recorded equalled 600 volts, and occurred about 4 P.M. on December 16.

The most noticeable feature in the curves of electrical disturbance during the period is that of the daily range of the instrument having attained a maximum usually between 8 to 10 P.M., the tension reaching over 400 volts at the time on the 17th, 18th, and 21st, and over 500 on the 22nd ult.

The fall in tension on the 25th was irregular and the value became almost zero at 6 A.M. on the 26th, for the whole of which day it continued low. Negative electricity was recorded for the first time from 1 to 3 A.M. on the 29th.

Undoubtedly the value of the tension of the atmospheric electricity, as measured by the Thomson electrometer is, as M. Descroix states, only a relative one. We have determined experimentally that with the same instrument the indicated tension is largely influenced by the distance of the nozzle of the water-dropping collector from the wall of the building in which the instrument is placed, and in accordance with a suggestion of Sir W. Thomson, we replace during the passage of thunderstorms our ordinary discharge-tube by a very short one, so as to get the scale of tensions within the range of the electrometer.

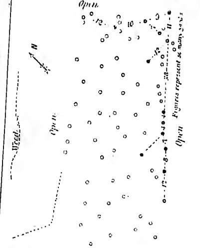
Kew Observatory, January 6 79 G. M. WHIPPLE

A thunderstorm of extreme violence is reported to have burst over Bayonne on the 15th Dec. at 8.30 a.m. The lightning struck the mast of a ship anchored in the roadstead, and broke it into 200 pieces. On the coast a tree was actually pulverised. The electric discharges were accompanied by a fall of hail which covered the ground with an ice layer 5 centimetres in thickness. The stones were homogeneous and transparent. Jan 79

(10) J. A. H. asks: 1. Is there any advantage in what lightning rod men call "circuit" rods—that is, two ground rods to one point? What do you think of such rods put into the ground 8 or 10 feet, ground tolerably dry? A. The only advantage in such an arrangement is that it affords a better ground surface. If the ground connections terminate in dry earth, the lightning rod will not prove effective. 2. Are horse shoe magnets better than common points, or should points be magnetized so as to lift small needles? A. There is no advantage in a magnetic point. 3. What is your opinion of tin roofs as a protection against lightning? How should they be connected with the ground? A. Tin roofs, if connected with the lightning rod having good ground connections, may prove an additional protection. The ground end of the rod should be forked and buried in earth that is continually moist. The effectiveness of the rod may be increased by filling the hole around the rod with pounded coke or charcoal. The ground end of the rod should be bent away from the house. 4. Is it safe to put a rod into a well? A. Yes. 79

Effects of Lightning May 79

A REMARKABLE electric discharge occurred on Sir Robert Gordon's estate of Letterfourie in a small wood about four miles to the south-east of this place on November 16 last about 12.45 A.M. The accompanying sketch (scale $\frac{1}{16}$" = one yard), where



the trees (common fir and larch) struck are represented by black dots, will give you an idea. The soil and trees were slightly covered with snow, which had been falling at intervals since sunset on the 15th. On that night I observed two or three flashes of lightning accompanied by thunder, and a few days afterwards I was told by a local medical gentleman, who had visited the spot, that some eleven or twelve trees had been struck among the hills under peculiar circumstances. The snow was lying so deep at the time that the place was well nigh inaccessible, and owing to want of leisure and the continued severe weather, I had no opportunity of visiting the wood in question until a few days ago. I then ascertained from a farmer living 150 yards south-east of the spot, that the trees must have been struck simultaneously.

Between 9 and 10 P.M. on the 15th a flash of lightning, followed by loud thunder, was seen by him in the north and clear of the wood altogether; besides, the interval between flash and peal showed it to be at a comparatively great distance. The man, being an invalid, never slept, when about 12.45 A.M. on the 16th a blinding light immediately followed by a tremendous thunder-clap made him think his own house was struck. The next and last flash and peal occurred a quarter of an hour afterwards at a considerable distance away to the west.

The effect of the lightning on the trees was observed from the window on the following morning, and as the spot was daily visited by the inmates of the house for the purpose of drying clothes, there could be no doubt but the damage had been done during the previous night. All the fourteen trees, varying from six to nine inches in diameter, and not visibly higher than the immediately adjoining ones have lost the bark over a width of one half to one inch, and the wood is slightly split.

Buckie, Banff, N.B., May 12 G. W. CAMPHUIS

63

It is the elementary part of a subject which is always so badly taught, chiefly because it is a general belief that any one can teach a child. We are, therefore, pleased to welcome in Parts I., II. and III., an exceedingly clear statement as to what sections of arithmetic should be taught, and how they should be taught to young children.

LETTERS TO THE EDITOR

A Machine for Drawing Compound Harmonic Curves

IN NATURE (vol. xx. p. 103) there appears an abstract of a paper by Prof. E. W. Blake on a machine for drawing compound harmonic curves. Prof. Blake is doubtless not aware that this machine is based on a plan proposed by Prof. Perry and myself in our paper on "the music of colour and visible motion," read before the Physical Society, November 23, 1878. In that paper, after the description of our own motion-compounder, will be found the following:—"But it is possible that in our new machine we shall adopt a totally different plan, and one which we think is new. If the two extremities of a long rigid rod have parallel motions perpendicular to the rod, the middle of the rod has a motion equal to half the sum of the extremities. Thus the parallel motions of 2, 4, or 2^n points may be compounded. Similarly for 3 points, one-third of the sum of parallel motions is obtained from the centre of a rigid triangular piece of which the points are the corners; so that by bars and frames of simple construction it is easy to get the sum of the parallel motions of any number of pieces."

But I think that this method which we suggested, and which is the one now described by Prof. Blake, is inferior to the roller-cam principle employed by us in the instrument we constructed, and explained to the Physical Society, in that with the latter in its complete form we can alter, while the machine is actually in motion, the *amplitude* as well as the *phase*, by any *desired* amount, of *any one* of the component vibrations. This facility, although not possessed, as far as I am aware, by any other motion compounder, is extremely desirable for the varied description of compound curves, whether these curves be merely intended, as in the ordinary forms of such instruments, to show the resultant of two or more vibrations, or be designed, in accordance with the plan of Mr. Perry and myself, to work on the emotions, in the rendering of a new genus of music, by the varied, yet controlled, motions of the body, or bodies, describing these curves. W. E. AYRTON

Lightning Conductors

ON the night of Wednesday, May 28, shortly after ten o'clock, my father's house at Caterham, in Surrey, was struck by lightning. We had not noticed any thunder before going to our bedrooms, but shortly after doing so we saw a very vivid flash, followed by thunder after an interval of perhaps five seconds; three or four minutes after this there came with a terrific crash the flash which struck the house, and afterwards no more thunder or lightning sufficient to attract our attention while we were intent upon investigating the mischief done.

The house stands high, upon a hill upwards of 700 feet above the sea; it is somewhat higher than any house or other object in its immediate vicinity. Roughly speaking, it may be described as a square block surmounted by a steep tiled roof, the ridge of which runs north and south, and astride upon the ridge stand two chimney stacks of equal height; from one corner of the square block runs away an extension, the roof and chimney stacks of which are upon a somewhat lower level.

Upon the northern chimney stack, at its eastern end, was the lightning conductor, which consisted of the usual hollow rod ($\frac{1}{2}$ inch) at the top, continuous with a flat plaited rope of copper and zinc wire (1 inch in width), carried through glass insulating rings along the slope of the roof, over the rain-water gutter, and down the side of the house into the ground.

The flash first struck the lightning conductor, hurled the rod down, and shattered the chimney-pots and a little of the brick-work; it seems to have followed the chimney-stack down to the ridge of the roof, and there to have divided. That portion of the discharge which passed down the eastern slope of the roof seems to have followed the chain portion of the lightning conductor as far as the rain-water gutter (iron); this it slightly broke, and broke also two panes of glass immediately beneath it, but this portion of the flash could be traced no further, and dead leaves, &c., about the remainder of the lightning conductor would seem to indicate that none had passed down that, at least not any large quantity.

The greater part of the discharge seems to have utterly left the guidance of the conductor, and to have first followed the lead flashing of the chimney stack down the western slope of the roof; a foot or so below the end of the flashing the roof was perforated, and the tiles broken and thrown down; thence, without any disturbance of the intervening tiling the discharge leapt a distance of some 15 feet, perforated horizontally a 9 inch-brick wall, covered on its exterior by weather tiling, and so reached an iron water cistern immediately within this wall. The woodwork about the cistern was started, but not much splintered; thence the discharge passed downwards by way of the water pipes, down two stories to a force-pump in the scullery, and thence, probably, by the pipes, down into the subterranean water-tanks.

But the pump in the scullery was provided with a pipe and tap over the sink, and there was also a small "tell-tale" pipe from the cistern above, designed to show when the cistern had been filled. This also terminated over the sink. Along these some part of the discharge was led, and not being safely conducted away, threw down and shattered the slate about the sink.

The perforation in the brick wall was circular, large enough to easily admit one's finger, and was blackened on its interior; when first found, eight or ten minutes after the occurrence, it was still quite hot.

The practical question that presses for an answer is, what did the lightning conductor do for us? Its selection as the point struck seems as though it brought the discharge upon the house; certainly it, although I believe of the usual construction, was utterly inadequate to carry off, or even direct the course of, the discharge, for a most copious and violently destructive discharge passed altogether from it and down over the opposite or western slope of the roof.

On the other hand, the iron water-tank and its pipe system proved adequate and safe conductors of the electric fluid, which left not the smallest trace of its passage along them until it reached the scullery sink, and there would presumably have done no harm, had it not been for the existence of the tap pipe, which led a portion of it astray. And on both faces of the house the iron gutters and rain-water pipes seem to have proved efficient conductors, for no violently destructive effects were manifested, save the breaking of two panes of glass after the electric fluid reached them. But as I am no electrician I can add nothing useful to the bare narration of the facts. I should add that the soot was very completely and violently ejected into the rooms from the chimneys of the stack struck.

CHARLES S. TOMES

P.S.—Subsequent closer examination of the portions of the lightning-conductor showed that there were traces of fusion of the hollow copper rod at its junction with the rope which had been inserted into it; the sectional area of copper here available for carrying the discharge seems to have been less than that in either the rod or the rope. Slighter traces of fusion existed here and there in the whole length of the rod. In its passage round the water-gutters the discharge cracked each one at its junction with the next segment; that is to say, the iron was cracked wherever the interposition of a little red lead to make the joint tight offered increased resistance to its passage, and the lead flashing of the roof was fused below the perforations in the brick wall, indicating that the whole discharge did not go through the wall to the iron water-tank.

THE effects produced by the recent thunderstorms are so interesting and instructive that I think it worth while to record the results of investigations which I have made personally or had made for me.

On May 31 there was published in the *Times* particulars of the damage done to the church at Laughton-en-le-Morthen, and the conductor was described as a thin corrugated tube of copper made

Copper and Iron Lightning Conductors.

What should be the relative sectional areas of lightning rods in order that neither metal should be more liable to fusion by the passage of an electrical discharge through it than the other? Mr. R. S. Brough (whose recent death in India we regret to announce) has answered this question in the May number of the *Philosophical Magazine*. The relation usually given—viz., that an iron rod should have four times the sectional area of the copper rod—is based on the fact that copper conducts electricity six times as well as iron, while the melting point of iron is about 50 per cent higher than that of copper, and $\frac{6}{1\cdot5} = 4$. This simple treatment is incomplete, because it neglects the following important factors: (1) The influence of the rise of temperature in increasing the electrical resistance of the metal; (2) the difference between the specific heats of the copper and iron; and (3) the fact that the iron rod being made several times more massive than the copper rod, it will require a proportionally greater quantity of heat to increase its temperature. Taking these considerations into account, Mr. Brough finds that the sectional area of an iron rod should be to the sectional area of a copper rod in the ratio of 8 to 3. For the same efficiency iron rods are therefore cheaper than copper rods.

June 79

THE MECHANICAL ACTION OF LIGHTNING.

Engineer July 2 1880

Within the last few days England has been visited by several thunderstorms of considerable severity, and deaths caused by lightning have taken place in three or four localities. Trees have been rent, animals slain, houses injured, and there is some reason to conclude that the summer of 1880 may become rather remarkable for the manifestations of electric disturbance taking place in Great Britain. Although it is well understood that thunderstorms are always to a certain extent dangerous; and although most buildings, public or private, of abnormal height are provided with lightning-conductors to protect them, very few persons know accurately what lightning is. That portion of the general public which is fairly well-informed, holds that a flash of lightning is a discharge of electricity from a cloud to the earth. The country journalist regards it as "a discharge of the electric fluid." The ignorant peasant speaks of a thunderbolt, and believes that an invisible something concealed in a "flash of fire" comes from the sky and slays or rends. If we turn to text books for information we shall find very little. "Lightning," writes Professor Fleeming Jenkin, "is an enormous electric spark passing between two clouds, or from a cloud to the earth." We shall see in a moment what it is that Professor Jenkin calls a spark, and we shall be able to judge whether the conditions are such that an electric spark and lightning are one and the same thing. But before going further we must ask our readers who may care to peruse this article to think a little for themselves. It is not probable that they can thus find out what a flash of lightning is, and it is certain that we cannot tell them, but we can at least show that it is possible to construct a theory concerning the phenomenon which is consistent throughout.

We may start by saying that lightning is unquestionably a form of electrical discharge, and it produces effects in all ways analogous to those produced by a discharge from a Leyden jar or other reservoir of high tension electricity. It has recently been urged that electricity is a mode of force. It is very difficult though not impossible to form a mental conception of a pure force, isolated and apart from matter; but be electricity what it may, it makes its presence known to our senses by its effect on matter; and there is, furthermore, reason to believe that matter which may be invisible or imponderable is first acted on, before that kind of matter with which mankind is more or less familiar. Let a Leyden jar—one large enough to hold about two quarts of water will answer very well—be fully charged, and then discharged through a sheet of thick pasteboard. If matters are properly managed a hole may be punched in this way through a thickness of about ⅛in. If this hole be examined it will be found that, although the edges may be singed, it has not been burned through, but punched through. The hole will be very like in its diameter to those made by a charge of No. 9 shot fired at a distance of 20 yards through a similar sheet of pasteboard. It is very difficult to conceive that such a hole has been made by the passage through the pasteboard of a pure force; all the evidence goes to show that something, that is to say, some form of matter, has gone through the cardboard and made the hole. If a piece of the pasteboard target, with one shot hole only on it, and the piece of card punched by the electric spark, were handed to a man who did not know anything of how the holes were made, he would say of both that something, either a shot or a rather blunt metal instrument, had been driven through the material and left the holes behind. There is, however, this to be noted, that in many cases the hole appears as though it had begun within the substance of the paper, and not at one side or both. It has been laid down that when an explanation of any phenomena or occurrence is available which satisfies all the conditions, it is unnecessary and illogical to offer theories based on any second hypothesis. The electrically punched hole is just such a hole as would be made by the passage of something material through the paper, and so far we have reason to believe that something material has passed through. Now, if we compare the effects of a Leyden jar spark with those produced by lightning, we find a strict similarity between them. The lightning is different from the Leyden jar spark not in kind but in magnitude. When stone is ground to powder, or a tree split, we are justified in asserting that matter in some form or other came in contact with the stone and powdered it. It is supposed that trees are split by the production of steam from their juices by the heat of the electric discharge; and when lightning strikes sand it often produces curious tubes of fused quartz called Ligurites. But allowing for this, a sufficient number of cases occur in which the effect produced is certainly not due to heat. At first sight these statements will perhaps seem to a few of our readers as extremely heterodox. They will say that we have here a theory of material thunderbolts, such as the ignorant peasants hold. Our reply is that there may be thunderbolts and thunderbolts, but that the peasant according to his lights has spoken and reasoned wisely. He has assumed that a great hole cannot be dug in the earth unless something of which the soil can take cognisance has operated upon it. We cannot form any conception of a hole being dug in a field by a pure force. Nor can we imagine such a mundane thing as a block of granite reduced to powder save by the impact or influence of something very different from a pure force. There may be forms of matter, however, susceptible to the operation of pure forces. We neither assert nor deny that such is the case, but it is more reasonable to suppose that when a stone is shattered or a hole pierced, or an excavation made, that it is made by some form of moving matter than by anything else. Lest it should be said that in assuming that the electric spark is a manifestation of matter in motion we are standing alone, we shall support our opinions by the following quotation from Prof. Fleeming Jenkin's "Electricity and Magnetism." "The distribution of electricity over bodies which have points or angles is such that the electric density becomes very great on these points as it would on a very small sphere, even when the potential is not high. The result is a great repulsion of the electricity for itself, or rather a great repulsion between the neighbouring parts of the matter charged with it. We then frequently see *the electrified matter passing off in the condition known as the electric spark.*" Again, in another place he writes:—"The electricity has such a repulsion for itself that if it accumulates sufficiently the force becomes great enough to break down the pressure of the air, and *highly electrified particles of the conductor and of air fly off the point. Every electrical spark seen is an illustration of this convection. Lightning is one example.*" The italics are ours. We are apparently justified then in saying that the hole was punched in our card by a volley of missiles despatched from the surface of the ball of the discharger, and that the mechanical effects of lightning are in like manner possibly due to a volley of missiles dis-

A New Theory of Terrestrial Magnetism.

Engineering July 9 1880

When Professor Rowland, of Baltimore, proved that a moving charge of electricity, such for example as might be obtained by rotating an electrified metal ball, behaved like a dynamic current, and had power to deflect a magnetic needle, Professors Perry and Ayrton based upon the fact a theory of the earth's magnetism in supposing that the earth was highly electrified, and became a magnet by virtue of its axial rotation. Professor Rowland, who had himself entertained the theory, however, showed that the terrestrial charge required by this theory was enormously greater than that believed to exist on the earth, and thus, though he did not completely dispose of the theory, at least did a great deal to discredit it as solely accounting for the earth's magnetism. A somewhat similar theory is now put forth by Professor Lemström, of Helsingfors, and founded on a like experiment. M. Lemström finds that when a ring of insulating material is rotated round its axis, it acts as a galvanic current, and produces a magnetic field within it. He explains this effect, according to Edlund's hypothesis, by supposing that the ether permeating space is dragged along by the ring, so as to create a vortex at the centre of the latter, and thus constitute a magnetic pole. In the same manner the earth being composed mainly of non-conducting materials, and constantly rotating, magnetic poles would be produced at or near the poles of motion.

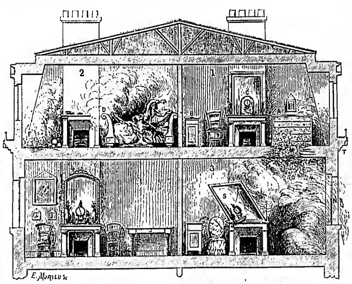
La Nature July 12

pait, après avoir fait sauter une persienne. Une petite fille, qui s'était abritée sous la porte, a été violemment jetée à terre, mais n'a heureusement eu aucun mal.

A Suresnes, place Henri IV, la foudre, tombant dans le restaurant Dubois, a effondré la toiture, démoli une cheminée et détérioré le compteur à gaz; une fuite de gaz considérable s'est produite.

Nous avons examiné en détail une des maisons qui a été atteinte par la foudre, celle de l'avenue de Clichy, nº 51; elle a été le théâtre de phénomènes très remarquables, dont le lecteur se rendra compte en jetant les yeux sur la gravure ci-dessous. La foudre paraît avoir pénétré dans la maison par un tuyau d'écoulement des eaux, situé du côté de la cour en T; elle a suivi la solive qui sépare le quatrième étage du cinquième. Dans la chambre nº 1, les carreaux du plancher ont été soulevés sous la commode A, dont le marbre a été cassé. Le globe de la pendule C a été percé d'un trou rond à travers lequel on peut passer le poing, le balancier de la pendule a été décroché et tordu, le marbre de la



Coupe de la maison frappée par la foudre pendant l'orage du 28 juin 1879 (nº 51, avenue de Clichy, à Paris). Figure servant à l'explication des phénomènes électriques

table de nuit B a été brisé. Une vieille dame qui buvait un bol de lait dans cette chambre a senti une secousse violente. Le plafond de la chambre du dessous (nº 3) s'est effondré, tout a été mis en pièces dans cette chambre, et les carreaux de la fenêtre N ont été brisés au milieu d'un nuage de poussière formé par les platras. La foudre a pénétré en même temps au cinquième étage dans la chambre nº 2. Une brave femme qui y habite, effrayée par les coups de tonnerre, s'était assise sur le bord de son lit et caressait son chien pour le rassurer; tout à coup la foudre a brisé son lit, le sommier est tombé à terre, et le pied du lit D a été haché comme à coups de tranchet. Les carreaux de brique, du sol de la pièce, ont été brisés en E et en F. Le témoin de ce phénomène raconte que le bruit a été effroyable, et que le dégât s'est accompli au milieu d'un nuage de fumée accompagné d'une forte odeur de poudre. La chambre du dessous, nº 4, n'a pas été atteinte. Le concierge de la maison a vu le coup de foudre; il se trouvait dans la cour, quand une lueur a passé devant ses yeux. Il a ressenti une vive commotion, et pendant plusieurs jours il s'en est trouvé incommodé.

REMARKABLE FIRE CAUSED BY LIGHTNING.

IN the storm of June 11th, at 10.00 A.M., lightning struck on the extensive wharf, of 1,000 feet front on the Schuylkill river, at the petroleum refinery of the Atlantic Refinery and Storage Co., located at Point Breeze, about four miles south of Market street, Philadelphia. This company has the most extensive petroleum refinery in the United States, and perhaps the largest in the world. Some accounts state that the electricity first struck the can store-house on the wharf. Others, with more probably correct statement, declare it struck first an immense pile of about 30,000 tin cans containing refined petroleum, exposed uncovered on the wharf, ready for shipment. Each wooden case contained two five gallon cans.

The *American Exchange and Review* says: The pile of cans was more probably the point of origin of the fire, because there was in it a great mass and large surface of metal to attract electricity, while all the buildings and tanks were well protected by lightning rods.

[There was, of course, the usual percentage of leakage from the cans, and we think it probable that the light vapor from the petroleum, which rises to a great height, formed the conductor which directed the lightning to the cans.]

The fire spread rapidly all over the wharf to the large packing and store houses and the superintendent's dwelling. Though great efforts were made to save the ships and barks lying at the wharf, five of them were consumed, two having full cargoes of oil on board. There were in a pump-house five or six large steam-pumps in excellent order, and there was no scarcity of water. Among the buildings and fixtures the fire burned over about 25 acres of space, covering the neighborhood for miles with dense black smoke, and the flames were not under control until about 5 P.M. A force of 40 men from the neighboring city gas works succeeded in beating back the flames from the piles of bituminous coal—partly with water, but mainly by shoveling earth upon them. This saved the gas works and tanks.

Sc. Am. Aug 2 1879

Only a small portion of the buildings, but many of the most valuable fixtures of the Atlantic Company were saved. Fortunately several large tanks containing 30,000 barrels each of petroleum, and partly sunk in the earth, escaped, though 12,000 barrels in a similar tank very near them were consumed. The destruction was about as follows:

Five ships and barks, owned in Europe; value, with two cargoes, say $125,000.

30,000 5-gallon cans of refined oil on the wharf.

One story packing house, 80x80 feet, and contents.

Two story can, soldering, and storage building, 50x100 feet.

Three story brick dwelling of superintendent.

One story frame cooper shop, 120x300 feet.

Boiler house.

Two story store house on wharf, 80 feet long.

Pump house, with 5 or 6 large steam pumps.

Many minor tanks full of oil, refining stills and boilers, and innumerable fixtures.

About 40,000 empty barrels were burned, and 20,000 were saved by the Schuylkill harbor police. The tugs New Castle and Churchman saved the large bark Magnum by towing her down stream. Various other vessels were saved.

It is stated that there was no insurance on the property of the refinery; $50,000 having expired last autumn and not renewed. The ships and cargoes were insured in part in Europe. The steam pumps and two stand pipes and 400 feet hose were all in good working order, but the fire so soon burned the pump house that the pumps were of no use.

The fire at the works of the Atlantic Refining Co., though subdued among the buildings on Thursday, the 12th, continued to burn among the cargoes of the ships Huron and Ilion. An effort was made on the 13th to tow the latter on to the mud flats of the western shore; but, by a sudden lurch of the burning vessel—she breaking in two—several hundred unburnt barrels of petroleum rose from her hull, ignited, and exploded. Instantly the river, for a long distance, was covered with blazing oil, so that the tugboat, Wave, escaped with difficulty. A strong westerly breeze blew the flames to the wharves of the Atlantic Petroleum Storage Co., on the east bank of the river, and these wharves and many sheds and their contents were burned. One storage shed was 500 feet in length, and contained a tank holding 500 barrels oil, and there were besides 1,000 barrels ready for shipment. The flames soon reached the sheds of the Empire Storage Company, and destroyed 40,000 empty barrels. Then 1,000 cords of pine wood, belonging to Lecompte & Perkins, were burned, and many thousand feet of rough planking.

About 3,000 feet of wharfing were consumed in this second fire; and all the losses in the two cannot be much short of $1,000,000. The oil continued to burn in some places, and on board the two vessels during June 14th and 15th. Several minor fires commenced in various places of the neighborhood, but were fortunately extinguished, and the great oil tanks, which were in such peril, and 200,000 barrels of oil at Point Breeze, were saved from destruction.

The wisdom of locating petroleum refineries and storehouses a long distance from the built-up portion of the city, is fully shown by this catastrophe.

Sc. Am Aug 2 1879

Telegraphic Ignition.

The telegraph wire as a fire risk has, perhaps, not received the attention it is entitled to. During a thunder storm which began at Council Bluffs, Iowa, soon after 11 o'clock, night of June 10, the freight office and warerooms building of the Chicago, Burlington and Quincy Railroad Company was burned to the ground, though most of the contents were saved. It was supposed that the fire was caused by a heavy charge of electricity entering the building along the telegraph wires. Probably all this loss would have been prevented had the ordinary lightning arrester been provided upon the posts near the building. The arrester is simply a wire that has one extremity placed very near but not in contact with the telegraph wire. The other extremity of the arrester terminates in the ground. When lightning gets on the telegraph wire it leaps to the arrester wire and passes into the ground.

LIGHTNING RODS NOT INSULATED.—Insulators should not be used in putting up lightning rods on buildings for protection against the electric current. The rod should be fastened directly against the building. But the most important precaution is to make sure that the bottom end of the rod has a large conducting surface in contact with the earth. Better have no rod than simply to stick the end a few feet down into dry earth; the proper way is to solder the bottom end of the rod to a metal water pipe or gas pipe in the ground. If there are no pipes, then make a long trench and put in some good conducting material, such as fine charcoal, or hard coal dust, iron ore, or old iron, making a good connection between the bottom end of the rod and this conducting material.

Manuf & Sc Press Aug 2 1879

LIGHTNING RODS.—Mr. R. S. Brough has been discussing, in the *Philosophical Magazine*, the proper sectional areas of iron and copper lightning rods. So far as mere conductivity is concerned, a comparatively thin wire of either metal would suffice for any conductor; but such a thin conductor would be dangerous, because it would be fused by a heavy discharge of lightning. Iron being more liable to be fused than copper, Mr. Brough sought to determine the relative sectional areas of rods of two metals, so that neither would be more liable to fuse than the other. Ordinarily, it is stated that the iron rod should have four times the sectional area of the copper rod. Mr. Brough shows that these areas should be as eight to three; or since the rods are invariably made circular, and circular areas are to each other as the square of their diameters, the diameters of iron and copper rods of equal effectiveness should be in the proportion of 1.63 to 1. Iron is, therefore, much the cheaper metal for lightning rods.

Manuf & Sc Press Aug 26 1879

A NEW METHOD OF LOCATING LIGHTNING RODS.

The Brockton (Mass.) *Weekly Gazette* contains a long account of a so-called wonderful discovery which has been made by Messrs. George S. and A. R. Prescott, of Merrimac, Mass. These gentlemen have ascertained that "lightning never strikes the earth except in localities directly over what may perhaps be best described as electrical currents on or below its surface, with which currents the electrical discharge invariably communicates. This has been determined by a multitude of tests made in localities widely separated. It follows, therefore, that in places where these currents are not found to exist, no danger need be apprehended, as in upward of four thousand instances, where tests have been made during the past three years, no record can be found of any exception to this universal rule."

This is certainly a wonderful discovery and merits careful attention. The subject is in the domain of science, and it can be reasonably presumed that the Messrs. Prescott have some knowledge of electricity, especially of earth currents, since their work is claimed to be in the detection of such currents. Moreover, these gentlemen must have made use of scientific methods, which past experience has shown to be indispensable; or they must have created a new method which rests on a scientific basis and is not dependent upon the freaks of the observer.

On careful inquiry we have ascertained that the Messrs. Prescott lay no claim to a knowledge of science. They are farmers, and have gained their knowledge of agricultural operations from actual practice in this pursuit, and not from mere theories. Whatever success they have obtained in farming has been due to the experience which has been handed down to them and by a lifetime of labor in their chosen pursuit. Without any knowledge whatever of electricity, they have suddenly made a discovery which puts to the blush the labors of scientific men in meteorology; have curbed, so to speak, the thunderbolts of Jove; have within their reach an immense fortune; and, more than all, have demonstrated that honest ignorance can discover what skilled education has overlooked. Their method also has never been employed or even thought of by scientific men. We shall first describe it in practical operation, and then devote a few words to its theory. Having cut a forked stick from a tree—any kind of wood will answer, although the discoverers prefer a forked stick from an apple tree, an elm, or a hazel—the two forks are grasped firmly with both hands, leaving the portion above the fork projecting skyward and not earthward. With the stick held in this manner, and with a look which may be described as sublunar, the operator walks over the ground to and fro, here a little and there a little, until he perceives that the projecting part of the stick begins to point downward. Then he stops and announces that there is an earth current beneath him. He does not know what an earth current is, nor how it usually manifests itself, nor what tests are usually employed, nor does he need to know, for the green apple tree stick decides the point. He must not, however, wear rubber boots; leather boots are preferable. In this way four thousand tests have been made and repeated; sometimes with a green apple stick, sometimes with an elm stick. Changing the character of the stick, however, appeared to make no difference. Further experiments, however, are needed to clearly establish this point.

When the stick points to the ground it is clear evidence that a lightning rod must be led to this point. If no earth currents are found by this method, the house in this locality is pronounced to be safe, and does not need lightning rods. The Messrs. Prescott form a marked exception to the old adage that "a prophet is not without honor save in his own country and among his own kindred," for no other "lightning rod man" is employed in the neighborhood of their native town, Merrimac, and their fame has spread far and wide. Treasurers and presidents of banks, city engineers, teachers in academies and schools, proclaim that, however impossible it may seem, they have been witnesses to the Messrs. Prescott's skill—perhaps we should say to Mr. Prescott's skill, for one of the brothers excels the other in this matter—and no amount of scientific skepticism can change their faith in Mr. Prescott's discovery. Hundreds of people are ready to testify to the fact that Mr. Prescott has repeatedly discovered places where lightning has struck in the past; and on being led by the oldest inhabitant into places remote from the Prescott homestead, has infallibly proclaimed to the awestruck observers, "Lightning once struck within four feet or less of this point." So much for the practice. Now for the theory.

It is claimed that "the human frame is the most sensitive to electrical influences of any organized form. Indeed, so far as cognizant to the sense and present knowledge, electricity seems to be the factor of the mysterious principle of life in the work of the human system." Mr. Prescott has a wonderfully sensitive organization. He has the hitherto unknown "electric sense," and he can, to speak metaphorically, smell electricity or taste it in the air or earth. He is not, however, the only person who has claimed to have this power. If he and his friends will procure a copy of Baron Charles von Reichenbach's "Physico-Physiological Researches in the Dynamics of Magnetism, Electricity, Crystallization, and Chemism," published in Partridge & Brittain's Spiritual Library, it will be found that Mr. Prescott belongs to the class called sick sensitives; in other words, to a class of persons whose systems are supposed to be peculiarly sensitive from disease to general cosmical phenomena. In the same book will also be found a long account of the use of a forked stick, which use is there called Blétonism, from the name of an agricultural laborer who had great success in its use. It is evident that agriculture is about to assert itself in the cognate field of electricity and magnetism. An account of the forked stick can also be found in Dr. Hutton's Mathematical Recreations, which is a translation with additions of Montucla's improvement of Ozanam's Recreations. An account of the virtues of the forked stick can also be found in Dr. Herbert Mayo's "On the Truths contained in Popular Superstitions" Letter XII. (London, 3d ed., 1851). It may interest Mr. Prescott to know that his forked stick has various names. It has been called divining rod, virgula divina, baculus divinatorius, baguette divinatoire, and the wonders accomplished by its use have been testified to by thousands of people for more than a century. If Mr. Prescott is a reader of fiction, he will also find an account of Douster Swivel's use of the forked stick in Walter Scott's novel "The Antiquary."

It is said by Mr. Prescott's believers that if he did not use such an absurdly simple contrivance as a forked stick he would have more followers and make a greater fortune. Indeed, it has been proposed that he should get up a complicated contrivance with a maze of wheels and electro-magnets, which should have nothing, however, to do with his method; but walking forth in boots (leather), with the stick and the machine, he should attribute the discoveries to the machine. Pessimists claim that he would then be in entire sympathy with the age.

Briefly let us sum up the claims of the Prescotts. We shall put the claims against the evidence in the following table:

CLAIMS.	EVIDENCE.
A forked stick in the hands of a sensitive person is a scientific instrument capable of detecting earth currents.	No evidence has ever been submitted to men capable of judgment on this point. The belief is supported only by invalids, and is an evidence of invalidism.

67

Mr. Prescott belongs to the class called "sick sensitives."	No medical school of any standing believes in the powers of the "sick sensitives" to discover occult phenomena. No master of his profession believes in such powers.
Earth currents have a determinate direction, and under the action of thunderstorms will always take the same direction.	Earth currents do not have a determinate direction, and the influence of a thunderstorm does not determine their direction.
The electric discharge seeks to unite itself with earth currents.	No evidence. This can only be determined by electrical tests, which Mr. Prescott and his friends are incapable of making, from utter ignorance of the subject of electricity.

The above is our statement of the case, and it is only justice to Mr. Prescott and his followers to state his case in the same manner, with a few comments, which can be taken or rejected.

CLAIMS.	EVIDENCE.
Four thousand test cases, more or less.	Tests made of twigs from three or more kinds of trees, all taken from different localities, and cut by unprejudiced observers.
The testimony of innumerable people, including teachers in high schools, civil engineers, and prominent business men of high standing and respectability. They have seen with their own eyes. They have been convinced beyond all doubt.	Respectability has always had great weight in deciding upon scientific matters. It is reasonable to suppose that if a bank president or cashier maintains his good standing in the community, his judgment on any subject, even on one to which he has paid no attention, is of value. Civil engineers and teachers can be summoned as experts in matters of scientific evidence.
Mr. Prescott has eminently the air of an honest man. He has been known man and boy by his neighbors for many years.	Honest looking men have never deluded themselves or deluded their neighbors.

In conclusion, the use of the forked stick is recommended to mining speculators and prospectors. Thousands of respectable persons in the past have testified to its efficiency in discovering lodes of precious metals, and it is one of the strangest facts in human history that mankind has stubbornly refused to discover precious metals by the use of such a simple means, and have forced themselves into what may be called complicated and theoretical scientific methods.

Nature

SECTION A—MATHEMATICAL AND PHYSICAL

On Lightning Protectors for Telegraphic Apparatus, by W. H. Preece.—For many years it was not the practice in England to protect telegraphic apparatus from the injurious effects of atmospheric electricity because the damage done was so insignificant, and because the remedy was found to be worse than the disease. But as telegraph systems increased, as the country became enveloped in one vast network of wires, it was found that the damage done became considerable, until, in fact, about 10 per cent. of the apparatus in use were in one year damaged.

Lightning protectors then became essential. Many forms were tried based on the fact that when a discharge takes place through a non-conductor such as dry air, at the moment of discharge the resistance along the line of discharge is practically nothing, and therefore all the charge is conducted away. According to Faraday, "the ultimate effect is exactly as if a metallic wire had been put into the place of the discharging particles" ("Researches," series xii.). Most of those tried failed.

The survival of the fittest has been exemplified in the "plate" protector. In this form—one of the earliest introduced—one thick plate of brass is in connection with the earth, and another similar plate in connection with the line, is placed above it, but separated from it by paper, or by insulating washers. The lightning entering the wire bursts across the paper or air-space in preference to passing through the apparatus, and thus escapes to earth.

An important modification of this plate discharger has been made by Dr. Werner Siemens, who, by serrating, or grooving with a pointed tool the opposing faces of the two plates at right angles to each other, converted them into a conductor which was supposed to be one composed of an infinite number of opposing points. The remarkable action of points in facilitating discharge is well known, and their introduction into lightning protectors occurred very early in the annals of telegraphy by Mr. C. V. Walker, F.R.S.

Messrs. Siemens's arrangement, very pretty in theory, never carried conviction of its value to the mind of the author, because protectors so prepared never singled themselves out as evidently superior to others that were not so prepared, and while the intersection of the grooves certainly formed mathematical points, they did not form physical or mechanical points, and it is upon the action of this latter kind of points that such remarkable electrical effects are produced.

Dr. Warren de la Rue having very kindly placed his well-known battery of 11,000 cells at the disposal of the writer, he prepared four plate-protectors identical in dimensions, excepting that two were serrated, and two were not. The two plates were separated from each other by narrow ebonite washers ·01 inch thick. The upper plate was placed in connection with the positive pole, and the lower plate with the negative pole. The number of cells were increased until a continuous current of electricity flowed.

1.—*Plain Plates*

Number of Cells.		Effects produced.
1,000	...	Slight sparks commencing on completing circuit.
1,080	...	Sparks evident.
1,200	...	Sparks frequent and abundant.
1,500	...	Continuous arc.

2.—*Serrated Plates*

Number of Cells.		Effect produced.
1,000	...	Sparks just commencing on making contact.
1,080	...	Sparks evident.
1,200	...	Sparks frequent.
1,500	...	Continuous arc, but fitful.

2,000 cells in each produced a continuous stream of electricity. The effect with 1,500 cells was decidedly more marked with the plain plates than with those serrated. The experiments were extremely pretty, and very decided in their character. Hence it appears that grooving is not only of no use, but that it rather deteriorates the value of the protector.

These experiments confirm very decidedly the accuracy of the figures obtained by Dr. Warren de la Rue and Mr. Müller of the striking distance between two flat disks given by them in their paper read before the Royal Society (*Phil. Trans.*, vol. 169), where it was shown that 1,200 cells struck across ·012 inch. Here 1,000 struck across ·01 inch, which agrees perfectly with the curve produced by those observers.

It is the practice in the Post Office telegraph department to keep these plates apart by thin paraffined paper ·002 inch thick, so that the air surface is really much thinner than that experimented upon, and the striking difference of potential only 250 volts.

Messrs. De la Rue and Müller have shown that for points and various kinds of surfaces opposed to each other, plane surfaces act the best for potentials less than 1,500 volts, and that points are only efficient for high potentials. Now as it is doubtful whether atmospheric electricity causes much higher potential than 1,000 volts, it is clear that plane surfaces are the most effective for protecting apparatus. It is quite certain that such plates, plain and smooth, separated by an air space ·002 inch thick, will form very efficient lightning protectors.

The author is very much indebted to Dr. Warren De la Rue for the performance of the experiments in his laboratory.

MÉTÉOROLOGIE ÉLECTRIQUE

Faits démontrant le développement de l'électricité avec la condensation des vapeurs.

Electricity Aug 30 1879

LETTRE

à la Rédaction de la Revue scientifique illustrée L'ÉLECTRICITÉ

Je ne peux pas laisser passer, sans une protestation de ma part, les paroles de l'illustre astronome français M. Faye, que je lis dans les *Comptes-rendus de l'Académie des Sciences*, 28 juillet 1879, page 107, quand il dit : « Quant à l'électricité, il n'est nullement établi que la condensation des nuages ou leur évaporation soit la source de leur électricité. »

Je prends la liberté de rappeler quelques faits que j'ai constamment observés, et qui ont été depuis confirmés par les expériences faites dans le cabinet :

1° Les grandes tensions électriques de l'atmosphère qui ne se peuvent plus mesurer avec les électromètres, que nous enregistrons avec le symbole de l'infini et qui se traduisent par de vigoureuses étincelles, se tirant des conducteurs isolés bien exposés, ont lieu exclusivement avec la chute des grandes pluies de neige ou de grêle. Ces chutes doivent se produire sur le lieu de l'observation ou à une distance qui, d'après mes observations, n'excède pas de 50 à 70 kilomètres. Ces fortes tensions naissent, disparaissent avec la pluie, durent autant qu'elle et s'évanouissent avec elle, suivant la loi que j'ai établie, et sur laquelle je ne crois pas nécessaire de revenir.

Franklin a vu, la première fois, l'étincelle au moment de l'apparition de la pluie, et les fortes étincelles de Dalibard, de Romas et de Richman correspondaient, sans doute, à des pluies, des grêles ou des neiges à distance.

En conséquence, une nuée qui se réduit en pluie est une vraie source d'électricité, de laquelle peuvent sortir de nombreux éclairs, sans qu'elle soit épuisée. Mais, à la fin de la pluie, les énormes tensions disparaissent et, sous la nuée, on trouve moins d'électricité que par un ciel serein.

Les nuées ne sont donc pas des conducteurs qui s'électrisent par influence, mais des corps qui produisent l'électricité quand ils se résolvent en eau et en neige ; et, quand cette électricité ne trouve pas moyen de se dissiper facilement par l'humidité de l'air ambiant, elle se traduit par des éclairs.

2° Les vapeurs aqueuses qui sortent d'un cratère volcanique, avec une énorme tension correspondant à une température de plus de 1.000 degrés centigrades. A cause de l'abaissement de température qu'elles éprouvent en entrant dans l'atmosphère elles se convertissent en panaches de fumée très-denses et elles développent une grande quantité d'électricité qui, dans certaines conditions, se manifestent sous forme d'éclairs, pareils à ceux que Pline le Jeune décrit dans son récit de l'éruption du Vésuve an 79, et que nous avons revu, à plus de cent fois différentes, briller au-dessus du cratère du volcan.

3° L'observatoire vésuvien se trouve lui-même bien des fois enveloppé de nuages, et jamais, quand ces nuages ne se résolvent point en pluie, je n'ai constaté de tension électrique supérieure à la normale du lieu.

4° Lors des rapides augmentations de l'humidité relative de l'air dans les nuits de forte rosée, j'ai toujours constaté de plus fortes tensions de l'air.

5° L'été, saison d'évaporation plus que de condensation, présente moins d'électricité que les autres saisons ; mais comme un même abaissement de température de l'air chaud et humide produit une précipitation plus abondante que dans l'air sec de l'hiver, les manifestations orageuses sont plus faciles et partant les coups de foudre plus nombreux.

6° Les vapeurs qui s'élèvent du sol doivent subir plus facilement dans les régions plus élevées une condensation par abaissement de température, condensation qui, sans troubler la pureté du ciel, peut augmenter l'électricité de l'air et agir sur les conducteurs exposés à son action, et donner des indications visibles dans les électromètres.

Les phases des périodes diurnes dépendent visiblement des mouvements des vapeurs dans l'air, il en résulte que le maximum du matin qui, à Naples, correspond à peu près à 9 heures, est à 8 heures à la hauteur de l'observatoire. Il en est de même pour le maximum du soir qui, à l'observatoire du Vésuve, précède également d'une heure le maximum de Naples.

7° Pour confirmer ce fait et beaucoup d'autres, que je néglige pour ne point allonger démesurément cet article, j'ai été conduit à tenter une expérience

(1) Nous renverrons l'auteur à ce que dit M. Poisson, tome Ier, seconde édition, contre l'usage impropre de ce mot, *force d'inertie*. Il est enseigné partout, du reste, que *l'inertie est une propriété de la matière qui consiste en ce qu'aucune molécule ne peut trouver en soi une cause de mouvement.*

ON LIGHTNING PROTECTORS FOR TELEGRAPHIC APPARATUS.

By Wm. Henry Preece, Electrician General Post Office.

Journal of the Telegraph Sept 16 1879

[Read before Section A, British Association, 1879.]

For many years it was not the practice in England to protect telegraphic apparatus from the injurious effects of atmospheric electricity, because the damage done was so insignificant, and because the remedy was found to be worse than the disease.

But as telegraph systems increased as the country became enveloped in one vast network of wires, it was found that the damage done became considerable; until, in fact, about ten per cent. of the apparatus in use were in one year damaged.

Lightning protectors then became essential. Many forms were tried, based on the fact that when a discharge takes place through a non-conductor, such as dry air, at the moment of discharge, the resistance along the line of discharge is practically nothing, and, therefore, all the charge is conducted away. According to Faraday, "the ultimate effect is exactly as if a metallic wire had been put into the place of the discharging particles." (Researches, series XII, 1406.) Most of these tried failed.

The survival of the fittest has been accomplished in the "plate" protector. In this form—one of the earliest introduced—one thick plate of brass is in connection with the earth, and another similar plate in connection with the line is placed above it, but separated from it by paper, or by insulated washers. The lightning, on entering the wire, bursts across the paper or air space in preference to passing through the apparatus, and thus escapes to earth.

An important modification of this plate discharger has been made by Dr. Werner Siemens, who, by serrating, or grooving with a pointed tool the opposing forces of the two plates at right angles to each other, converted them into a conductor which was supposed to be one composed of an infinite number of opposing points. The remarkable action of points in facilitating discharge is well known, and their introduction into lightning protectors occurred very early in the annals of telegraphy, by Mr. C. V. Walker, F. R. S.

Messrs. Siemens' arrangement, very pretty in theory, never carried conviction of its value in the mind of the author, because protectors so prepared never singled themselves out as evidently superior to others that were not so prepared; and while the intersection of the grooves certainly formed mathematical points, they did not form physical or mechanical points; and it is upon the action of this latter kind of point that such remarkable electrical effects are produced.

Dr. Warren de la Rue having very kindly placed his well known battery of 11,000 cells at the disposal of the writer, he prepared four plate protectors, identical in dimensions, excepting that two were serrated, and two were not. The two plates were separated from each other by narrow ebonite washers .01 inch thick. The upper plate was placed in connection with the positive pole, and the lower plate with the negative pole. The number of cells was increased until a continuous current of electricity flowed.

1.—PLAIN PLATES.

No. of cells.	Effect produced.
1,000	Slight sparks just commencing on completing circuit.
1,080	Sparks evident.
1,200	Sparks frequent and abundant.
1,500	Continuous arc.

2.—SERRATED PLATES.

No. of Cells.	Effect Produced
1,000	Sparks just commencing on making contact.
1,080	Sparks evident.
1,200	Sparks frequent.
1,500	Continuous arc, but fitful.

2,000 cells in each produced a continuous stream of electricity. The effect with 1,500 cells was decidedly more marked with the plain plates than with those serrated. The experiments were extremely pretty, and very decided in their character.

Hence it appears that grooving is not only of no use, but that it rather deteriorates the value of the protector.

These experiments confirm very decidedly the accuracy of the figures obtained by Dr. Warren de la Rue and Mr. Muller on the striking distance between two flat discs, given by them in their paper, read before the Royal Society (Phil. Trans., p. 169, 77), where it was shown that 1,200 cells struck across .312 inch. Here 1,000 cells struck across .01 inch, which agrees perfectly with the curve produced by these observers.

It is the practice in the Post Office Telegraph Department to keep these plates apart by thin paraffine paper, .002 inch thick, so that the air space is really much thinner than that experimented upon, and the striking difference of potential only 250 Volts.

Messr. De la Rue and Muller have shown that for points and various kinds of surfaces opposed to each other, plain surfaces act the best for potentials less than 1,500 Volts, and that points are only efficient for high potentials. Now, as it is doubtful whether atmospheric electricity causes much higher potential in telegraph wires than 1,000 Volts, it is clear that plain surfaces are the most effective for protecting apparatus. It is quite certain that such plates, plain and smooth, separated by an air-space .002 inch thick will form very efficient lightning protectors.

The author is very much indebted to Dr. Warren de la Rue for the performance of experiments in his laboratory.

USEFUL AND SCIENTIFIC NOTES.

Eng Mechanic Dec 26 1879

Case of Lightning-stroke.—A paper was read at a late meeting of the Clinical Society by Dr. G. Wilks, of Ashford, on a remarkable case of lightning-stroke, which occurred on June 8th, 1878. A farm labourer was struck by lightning while standing under a willow tree, close to the window of a shed in which his three fellow-workmen had just taken shelter from a violent storm of rain. His companions found the tree partly denuded of its bark, and the patient's boots standing at its foot. The patient himself was lying on his back two yards off, and though he was fully clothed previously, he was now naked, with absolutely nothing on except part of the left arm of his flannel vest. He was conscious, but much burnt, and his leg was badly broken. The field around was strewn with fragments of the clothing; the clothes were split or torn from top to bottom, the edges of the fragments being often torn into shreds or fringes; they only showed evidences of fire where they came in contact with metal, such as his watch and the buckle of his waist-belt. There were no laces in the boots. The left boot was torn and twisted into fantastic shapes, but the sole was uninjured, and there was no sign of fire upon it; the right boot had the leather much torn and the sole rent and burnt. The watch had a hole burnt through the case, and the chain was almost entirely destroyed. The stockings were split down the inner side; the hat was uninjured. The patient stated that he was struck violently on the chest and shoulders, became enveloped in a blinding light, and was hurled into the air, coming down on his back "all of a crash," and never losing consciousness. The hair of his face was burnt, and the body was covered with burns. Down each thigh and leg was a broad crimson indurated band of burning, passing along the inner side of the knee, and ending below the left inner ankle and at the right heel; a lacerated wound, with a comminuted fracture of the os calcis. The bones of the right leg were fractured, and the tibia protruded through the skin in the course of the burn. He was discharged healed twenty weeks after the occurrence. Dr. Wilks remarked on the almost complete exemption from injury of the nervous system and on the probability that the clothes being wet acted as good conductors, and so diverted the electric current from the great nervous trunks, thus saving the man's life.

The Great Northern Railway Company has adopted a system of lighting railway carriages for long distances by gas, compressed in vessels containing naphthaline.

ATMOSPHERIC ELECTRICITY.

Electrician Aug 7/1880

Notwithstanding numerous researches, some of which already date a century back, the laws by which atmospheric electricity varies, are not yet established. Nevertheless, a knowledge of these laws is the first step towards the understanding of the true cause of this important phenomenon. A valuable contribution to the subject has just been made by M. Mascart, and communicated to the French Academy.

The apparatus employed by him consists of a Thomson quadrant electrometer, in which the movements of the needle are transmitted by mechanical means to a pencil which draws lines on a band of paper at very close intervals. Both pairs of quadrants are maintained at equal potentials and contrary signs by the poles of a battery, whose middle plate is connected to earth, and the needle is in connection with an insulated vessel which allows of water to flow into the outer air. In short, the arrangement is connected to the well-known "water-dropping collector" of Sir William Thomson's design.

This arrangement presents the advantage that the deviations of the needle are equal on both sides of zero for changes of equal and contrary sign. The angular displacement of the needle is small enough under ordinary circumstances to remain sensibly proportional to the potential of the needle, that is, to the potential of the air at the point where the vein of water issuing from the vessel breaks into drops.

The curves then obtained have not the continuity which belongs to most other meteorological observations, and they often present sudden variations ranging from one end to another of the scale within a few minutes of time.

The examination of these curves, from the point of view of accidental changes, confirms a number of facts already known. The potential of the air is generally positive, particularly when the sky is pure. In cloudy weather the potential diminishes, shows rapid changes in degree, and is occasionally negative in kind. Rain almost always gives great negative deviations. The approach of a storm betrays itself oftenest by a great negative variation, followed by oscillations of great extent in the two directions, with a marked predominance of negative potentials. Positive rains are extremely rare, and never occur without storms.

It is manifest that accidental variations, great and little, ought not to enter into the reckoning if it is desired to find the normal course of the phenomenon. The simple appearance of the graphic lines on the paper permits of this course being readily seen; and the mean of a number of observations can be readily determined.

The phenomena observed by M. Mascart since January last are in agreement with the results obtained by him last year. The apparatus is installed at the College of France, that is to say, in the heart of a great city, and it might be objected that different results would be obtained in the open country. But M. Mascart affirms, on the strength of numerous experiments, that, save in the case of great perturbations, the seat of active electric masses is very far distant from the surface of the soil, and it is probable that the influence of a city does not cause much disturbance on the daily course of atmospheric electricity.

In its mean condition, the potential of the air, always positive, is much more elevated, and more uniform by night than by day. From nine in the evening to three in the morning it varies little. It lowers at sunrise, takes a minimum value at three p.m., rises rapidly afterwards, and attains a maximum about nine p.m.

There is thus only one minimum during the day and one maximum, almost constant during a great part of the night. That is to say, there is only one daily period, at least when we consider the most important term of the phenomenon. The amplitude of daily oscillation is notably more feeble during winter. The exceptional cold of December, 1879, would have had peculiar interest in connection with M. Mascart's experiments; but, unfortunately, the precautions taken against the freezing of the water in the collector did not prove sufficient to prevent congelation.

M. Mascart is of opinion that there is a relation between the electric state of the air and the temperature, but it will be necessary to possess several years' observations to establish that relation with rigour, and to study all the details of it.

The existence of the maximum of the night is in disaccord with the rule generally adopted. It is generally believed, since the experiment of M. Quetelet on the subject at Brussels, that there exists two daily maxima of atmospheric electricity, one in the morning and one in the evening, as well as two minima, one in the day and the other in the night. If M. Mascart's results are to be relied upon, this discordance would seem to be due to the method of observation adopted by M. Quetelet, unless, indeed, there are two maxima and two minima per day at Brussels.

M. Mascart's direct observations were made by day, and the nightly minimum inferred from them without being directly observed. But this minimum has been observed by other experimenters, either directly or by means of registering apparatus.

One cause of error which M. Mascart deems too frequently neglected is the insulation of the apparatus. An electrometer electrified by a temporary influence, and put in communication with water-dropping apparatus, only falls short by an unknown fraction, sometimes very slight, of the potential that it ought to have were the loss by the supports neglectable. But the insulating power of ordinary supports, stems of glass for example, varies much with the conditions of the atmosphere, and several courses combine to augment their conductivity during the night. It is necessary, therefore, to employ supports having an insulating power as perfect as possible and independent of all atmospheric conditions. Such a source of leakage may account for many misconceptions in similar researches.

J'aurai à vous communiquer des observations intéressantes sur l'électricité atmosphérique, mes observations ne sont pas terminées; seulement, ce que je puis vous [illegible] c'est au sujet des paratonnerres.

Cette question est loin d'être connue comme elle [illegible] rait de l'être, et ce qui m'étonne, c'est de voir des mai[sons] soi-disant sérieuses, vendre et appliquer des anneaux [de] cristal, qui s'enfilent jusqu'à la base de la tige: je serais bien curieux de savoir de quelle façon ils expliquent l'utilité de cette bague.

Je me réserve de revenir d'une façon toute spéciale sur l'installation des paratonnerres et de leurs effets réels, dès que mes expériences seront terminées.

En attendant, je vous signale que j'ai banni de toutes mes installations de paratonnerres les pointes rondes en cuivre jaune. J'emploie une pointe que j'ai inventée depuis trois ans. Cette pointe est en cuivre rouge forgé et a la forme d'une baïonnette, c'est-à-dire triangulaire de la base au sommet et terminée par une pointe aiguë en platine, quoique je sois ennemi du platine; je lui préférerais l'or, mais la routine est si difficile à vaincre! j'espère cependant, avec le temps, en venir à bout. Du reste, avec cette pointe, telle qu'elle est construite, l'écoulement du fluide électrique se fait aussi bien sur les angles qu'au sommet, suivant la tension plus ou moins grande de l'état électrique atmosphérique. J'ai plusieurs formes de pointes dans le même principe, et vous comprendrez sans peine que toute l'électricité qui peut passer par le conducteur et la tige, s'écoule librement par une pointe de ce système. Du reste, j'en ai appliqué une de ce genre à l'Observatoire du Pic-du-Midi, l'année dernière, et elle paraît bien se conduire, au dire du général de Nansouty.

J'ai apporté plusieurs perfectionnements à l'installation des paratonnerres dont je vous parlerai ultérieurement.

La pointe dont je vous parle plus haut remplace les pointes multiples avec avantage, et le prix en est modique puisqu'elle ne coûte pas plus qu'une pointe ronde.

J'ai aussi à l'étude deux problèmes très-importants:

1° Transformer la chaleur solaire; pouvoir l'emmagasiner et s'en servir quand besoin sera, soit en électricité, lumière ou chaleur.

2° Transformer l'électricité atmosphérique et l'emmagasiner pour s'en servir au besoin; l'électricité tellurique serait dans le même cas. Des expériences préliminaires me confirment que le problème est possible, et je le crois même facile. Si ces expériences peuvent vous intéresser, je suis prêt à vous les décrire; peut-être qu'en les publiant, la question ferait-elle de rapides progrès.

Je retourne au Pic-du-Midi dans le courant d'août pour installer à nouveau un deuxième paratonnerre au sommet du Pic; j'ai préparé des expériences à faire sur place; dès mon retour, je m'empresserai de vous les communiquer.

En attendant, recevez, monsieur, l'assurance de ma considération très-distinguée.

A. Brenis.

Bordeaux, 30 juillet 1879.

Nous recevons d'un de nos abonnés la lettre suivante sur laquelle nous appelons d'une façon insistante l'attention de l'administration:

En ma qualité d'abonné à votre estimable journal, je me permets de vous demander quelques renseignements, voire même quelques réflexions, au sujet de l'affaire suivante:

Une personne de ma connaissance, désirant établir une communication téléphonique entre son établissement et une succursale située à 50 *mètres* de distance, a demandé l'autorisation à l'administration des postes et télégraphes. Voici la copie de la réponse qui lui a été envoyée du ministère des postes et télégraphes et renfermant les conditions moyennant lesquelles il pourra établir la susdite ligne:

« Le concessionnaire d'une ligne téléphonique doit consentir à payer annuellement, à titre d'abonnement et pour droit d'usage, la somme de *cinquante francs* (50 fr.) par *kilomètre de fil* et 25 fr. par poste TÉLÉGRAPHIQUE (sic). Les frais de timbre, d'enregistrement, etc., sont aussi à sa charge. »

La personne en question désirerait savoir si une ligne inférieure en longueur à 1 kilomètre paiera également 50 fr., ou bien si ce chiffre est modifié selon la longueur de la ligne; dans ce cas, une ligne de 50 mètres ne devrait payer que 2 fr. 50. Mais si une fraction de kilomètre doit payer autant que le kilomètre entier, c'est-à-dire 50 fr., il résulte de là que l'installation dont je vous parle coûtera 100 *fr. par an*. Ce chiffre me paraît exorbitant et ridicule, car il dépasse de beaucoup le prix de revient de l'installation téléphonique et, de plus, il faut le payer *chaque année*.

Comme vous voyez, on exige d'abord 50 fr. par kilomètre de ligne pour la location et, en plus, 25 fr. par poste télégraphique. Pourquoi ces 25 fr. par poste et que signifie ce mot TÉLÉGRAPHIQUE que j'ai doublement souligné dans la copie que je vous donne d'autre part? Est-ce qu'il ne serait pas plus exact de dire *poste téléphonique*? ou bien croit-on que, dans chaque poste téléphonique, se trouvera en plus un télégraphe à cadran ou autre?...

Tout cela me paraît singulier, et si M. Cochery a l'intention de grever les installations téléphoniques de pareils impôts, je crois qu'il réussira plutôt à en étouffer la propagation. Les installations téléphoniques doivent payer un impôt; cela semble assez juste; mais cet impôt devrait être *relativement très-minime*.

S'il doit en être autrement, j'espère bien, Monsieur, que votre respectable journal, si éloquent et si juste, élèvera la voix contre un pareil abus. Il réussira certainement à modifier profondément cet état de choses, et j'espère bien qu'un jour les gens de progrès vous remercieront d'avoir contribué à la propagation de l'invention la plus merveilleuse de ce siècle.

Agréez, etc.

A. Darès.

On nous apprend que le Congrès télégraphique vient de terminer ses travaux. Une nouvelle convention aurait été signée le 28 juillet, et elle remplacerait, à partir du mois d'avril 1880, celle qui est en vigueur jusqu'à présent.

Le changement le plus important serait une modification heureuse entre les Etats limitrophes. Le tarif par mots aurait été accepté dans ce cas, sauf une surtaxe.

Ce tarif restera forcément en vigueur jusqu'en 1884; c'est au mois de juin 1884 qu'aura lieu la première réunion du congrès qui se tiendra à Berlin. Ce choix n'aurait sans doute pas eu lieu si la presse s'était plus vivement préoccupée des intérêts qui se discutaient à Londres, et si le huis-clos, dont nous nous sommes plaint, n'avait empêché de suivre le détail des délibérations.

Ajoutons que le tarif très-élevé qui est encore en vigueur entre l'Algérie et la France va être modifié grâce à l'initiative personnelle du gouverneur général. La taxe sera réduite à 10 centimes, ce qui conduira, suivant toute probabilité, à un trafic quadruple et nécessitera, nous écrit-on, la pose d'un nouveau câble entre l'Algérie et la mère-patrie. Cette mesure sera considérée comme un bienfait par tous les Algériens, et la pose du nouveau câble, une garantie de plus que les rapports télégraphiques ne sauraient être interrompus.

L'Electricité

HISTOIRE DE L'ÉLECTRICITÉ atmos

Il est important de faire remarquer que, pendant le triste été que nous parcourons, les grêles ont été très-rares, quoique les pluies aient été presque incessantes et qu'on ait éprouvé un abaissement constant de température.

Cette observation confirme la théorie bien connue de la formation de la grêle par l'influence de l'élec-

Dans ce même numéro, M. Jamin ne donne pas des nouvelles de sa fameuse chandelle, mais il se console de ses déboires en publiant une *note* sur ce qu'il appelle *l'imperméabilité magnétique du fer*. Afin de triompher sans peine, M. Jamin suppose que quelques personnes ont mis en doute la propriété du fer de paralyser l'action magnétisante d'une hélice. Il publie le résultat d'expériences qui convainquent d'imbécillité ces ennemis imaginaires. Mais il ne souffle mot des hérétiques qui se refusent à acclamer les vertus lumineuses de sa bougie miraculeuse !

M. Berthelot publie un nouveau chapitre de thermo-chimie sur les amalgames alcalins et *l'état naissant*. Mais il ne dit pas un mot d'électricité, à côté de laquelle il passe sans détourner la tête.

Cependant, il n'est pas nécessaire d'être doué d'une dose formidable de bon sens pour reconnaître que *l'état naissant* est un non-sens si l'on ne fait intervenir l'électrisation produite lors de l'action chimique. Tant que les gaz sont chargés de fluides électriques libres, ils sont à l'état naissant. Si on les met en position de conserver leur tension, l'état naissant persiste. La pile est une machine qui recueille l'électricité produite par l'état naissant, etc., etc.

Mais l'explication de ces phénomènes par les réactions *endo-thermiques* ou *exo-thermiques* paraît plus simple et plus logique.

Dans le numéro du 16 juin, nous devons signaler une idée émise, il y a quelques années, par un autre physicien, mais développée avec logique par M. Altramare.

Ce physicien cherche à expliquer la suspension des nuages *par leur état électrique*.

Rien n'est plus naturel. En effet, les masses nuageuses semblent former des objets définis dans l'atmosphère. Comme leur surface est conductrice, ils se chargent d'électricité qui agit, soit sur l'électricité négative de la Terre, soit sur l'électricité positive du sol, soit sur l'électricité des autres nuages.

Un ballon, suspendu dans l'air et recouvert d'humidité, doit se trouver dans le même cas.

Qui sait si l'attraction de l'électricité négative du sol n'expliquerait pas certaines chutes rapides quand le ballon est humide, ou quand la surface inférieure est le siége d'une évaporation active, comme lorsque le globe aéronautique passe au-dessus des forêts ? Il en serait de même dans le courant d'une ascension maritime.

Mais, pour avoir une opinion décisive à cet égard, il faudrait que le ballon fût conduit avec une régularité telle qu'on se rendît compte des causes qui peuvent déterminer sa descente ou son ascension.

Malheureusement, l'art n'a point fait assez de progrès pour que l'aéronaute le plus habile soit en état de déterminer la nature des forces troublant l'équilibre qu'il doit avoir établi avec son aérostat.

M. L. Hugo a cru reconnaître que la lumière électrique favorisait l'éclat rouge des pieds du *Nidularium*, et qu'au contraire, l'éclat du rouge du *Caladium* semblait avoir été terni.

Il serait facile de répéter l'épreuve et de se former une opinion à cet effet.

Nous signalons à nos abonnés la question que M. Léopold Hugo a posée au monde savant.

L'Académie a nommé une commission, composée de six membres, pour rédiger un rapport sur les observations que M. l'amiral Serres a recueillies pendant la campagne d'exploration de la *Magicienne*.

La commission daigne nous apprendre que des observations magnétiques ont été faites à bord, mais elle ne croit pas qu'il soit nécessaire d'ajouter un résumé des faits intéressants que les mouvements de l'aiguille aimantée doivent lui avoir révélés.

Quant aux observations électriques, il n'en est point fait mention.

Cependant, Arago, dans ses *Instructions sur les voyages scientifiques* (Tome IX de ses *œuvres*), n'oublie pas de mentionner la nécessité d'observer les coups de foudre et les aurores boréales.

Espérons que l'omission est du fait des rapporteurs et que le voyage de la *Magicienne* contiendra un nombre d'observations du plus haut intérêt...

Enfin, nous devons rapporter à l'électricité un mémoire de M. Dieu sur l'*Application inexacte d'un théorème de dynamique pour expliquer le mouvement des ailettes du radiomètre*.

MM. Bertin et Garbe, après avoir établi qu'un radiomètre suspendu par son axe se mettait en mouvement, ont cru avoir le droit de déclarer académiquement *que les mouvements du mobile étaient uniquement dus au fameux bombardement moléculaire du gaz, qu'ils avaient pris tant de soins pour extraire de la boule diaphane*.

Dans quelques pages serrées, M. Dieu a fait justice de cette manière peu logique de raisonner.

Il ne lui a pas été difficile de montrer que les deux associés avaient oublié de tenir compte du mouvement du résidu gazeux qu'il n'ont pu extraire, et dont ils ne devraient point faire abstraction, surtout avec la théorie bizarre qu'ils ont adoptée.

Il a montré ensuite que les forces extérieures ne sont pas du tout nulles, comme le supposent les équations des deux associés.

Enfin, il a montré l'importance d'une autre condition essentielle, dont ils oublient de tenir compte, quoiqu'ils l'aient, si nous avons bonne mémoire, signalée au monde savant.

Si l'on arrête le mouvement de l'aiguille dans sa chappe, le mouvement du tourniquet est paralysé.

Aucune de ces observations ne s'oppose à ce que le mouvement de la roue de mica soit produit par l'électricité.

M. Dieu termine sa très-intéressante communication en demandant :

1° Que l'on varie les substances de chaque palette et de ses faces en cherchant à étudier l'influence des pouvoirs réfléchissant, phosphorescent ou calorifique des deux faces;

2° En modifiant la nature des rayons lumineux, et notamment en les polarisant;

3° En suspendant le globe sur des pointes très-fines et en le renfermant dans un récipient en verre où l'on ferait le vide.

Il est bon de noter que M. Crookes s'abstient d'envoyer dorénavant à l'Académie les communications insignifiantes à l'aide desquelles il bombarde *non moléculairement* la Société royale de Londres.

On peut considérer cette abstention comme un premier succès; car il est déplorable de voir l'inventeur d'un si admirable appareil s'attacher à diminuer sa gloire, à l'anéantir, en s'acharnant à soutenir une théorie contre laquelle proteste le bon sens, ce grand instrument d'analyse dont personne au monde, fût-il à la fois membre de l'Académie des Sciences de Paris et de la Société royale de Londres, ne saurait se passer, quel que soit son génie.

MÉTÉOROLOGIE ÉLECTRIQUE

La Météorologie électrique au Congrès météorologique international de Rome

Lettre du directeur de l'observatoire Vésuvien aux secrétaires de la Rédaction du journal *l'Electricité*.

Puisque les actes du Congrès météorologique de Rome n'ont point été régulièrement publiés (1) avec l'extension qui serait nécessaire, j'ai pensé à informer la rédaction de votre excellente Revue, de ce qui s'y est passé, relativement à l'observation de l'électricité atmosphérique.

Au Congrès de Vienne, on avait eu quelques discussions sur les méthodes et sur les appareils les plus propres à ce genre d'observation. Il y eut des membres qui proposèrent l'électromètre Peltier et d'autres l'électromètre Thompson avec la veine descendante; enfin, quelques-uns recommandèrent mon électromètre bifilaire avec l'appareil à conducteur mobile. Le professeur Cantoni fut chargé d'étudier

(1) Nous demanderons de quel droit les commissaires se sont abstenus de mettre le monde savant à même d'apprécier la profondeur de leur science et la sagesse de leurs délibérations. Tant de modestie dépasse leur mission.

mais empêchera l'insecte qui sèche les feuilles de sécher nos fleuves et de changer son nom de phylloxera en potamoxera (1).

P. DESMAREST.

L'Electricité

L'orage du 6 septembre à Laigle

Nous avons eu occasion de contrôler par nous-même la parfaite exactitude des renseignements renfermés dans l'article suivant, dû à la plume d'un praticien distingué, qui a fait de l'étude de la nature le but de ses loisirs. Il serait bien à désirer que l'exemple donné par M. Jules Houyer, ancien maire de la ville de Laigle et auteur de nombreuses observations météorologiques, fût plus fréquemment suivi.

Dans la nuit du 6 septembre, un orage est venu s'abattre sur la ville de Laigle, vers deux heures du matin. Dès une heure, les éclairs ont commencé à illuminer le ciel vers l'Ouest, puis, en se rapprochant, ont été promptement suivis des grondements du tonnerre, tantôt sourds et prolongés, tantôt secs et éclatants. A deux heures et demie, la pluie tombait par torrents, et l'eau venait affluer abondamment dans les parties basses de la ville. Tout semblait fini, ou du moins tirer à sa fin, lorsqu'un second orage, venant de la même direction, est venu ranimer la scène d'une façon plus énergique; ce second orage se trouvait en plein au-dessus de la ville de Laigle. Vers trois heures et demie, une nouvelle pluie diluvienne est survenue, plus abondante que la première. On entendait les coups de tonnerre plus rapprochés, plus éclatants.

A quatre heures et demie, la foudre est tombée dans le quartier de la Porte-Rabel, sur une des maisons placées au bord de la route de Mortagne.

Cette maison, qui appartient à M. Lacroix-Verrier, est occupée par deux ouvriers fendeurs, MM. Godet père et fils et par deux enfants; elle se compose de deux pièces au rez-de-chaussée, et elle est surmontée d'un petit grenier. Elle forme la moitié d'un corps de bâtiment complété par un autre logement de même disposition.

La foudre est tombée sur une cheminée qui forme une pointe regardant le sud-est; la cheminée a été démolie à sa partie supérieure et les débris sont tombés dans le grenier, au-dessous de la pointe, et par le conduit de la cheminée, puis la foudre a continué son trajet en descendant par la cheminée, démontant un tuyau de poêle qui y aboutissait.

Arrivé au sol, à *un mètre* seulement du lit où étaient couchés le père et le fils, le fluide électrique fit éclater plusieurs carreaux en terre recouvrant le sol, et un fragment assez gros fut lancé sur la tablette de la cheminée.

En même temps, les carreaux volèrent presque tous en éclats.

On remarque aussi plusieurs carreaux de faïence enlevés à un potager placé près de la cheminée, du côté opposé au lit.

La foudre passa de là dans la seconde pièce, où se trouvaient couchés deux enfants, dans le même lit, et, sans causer aucun dégât, sortit par un carreau de la fenêtre, remontant sur l'entablement et suivant une gouttière en fer-blanc jusqu'à une lucarne placée près de l'autre extrémité du bâtiment. On remarque quelques briques enlevées et projetées au loin, provenant du bas de cette lucarne; quelques tuiles sont cassées à son sommet.

Les quatre personnes habitant ces deux pièces, d'ailleurs assez petites, n'ont pas éprouvé le moindre mal.

L'examen des lieux et l'innocuité de la foudre en ce cas semblent indiquer qu'il s'agit d'une variété de la foudre connue sous le nom de *tonnerre en boule*.

D'ailleurs, une des enfants déclare avoir vu passer sur le sol un corps lumineux, *gros comme un petit ballon*.

Dr JULES ROUYER.

Nous ajouterons que la présence du poêle en fonte qui, comme on le voit plus haut, se trouvait dans la cuisine, et le voisinage du fil télégraphique peuvent avoir été les causes déterminantes de la chute de la foudre.

Car on sait que les masses métalliques constituent un danger spécial, lorsqu'elles cessent d'être en rapport avec le réservoir commun.

On nous a affirmé qu'il n'y avait, dans toute la ville de Laigle, petite ville excessivement industrieuse où le travail du fer est si répandu, qu'un seul paratonnerre, tant l'usage de ces appareils est encore peu répandu dans une contrée montagneuse où le travail des métaux est une industrie florissante.

Dans de pareilles circonstances, on ne doit point s'étonner que les observations fulgurales soient fréquentes, et nous sommes persuadé que M. Jules Houyer aura plus d'une fois l'occasion de nous communiquer des faits dignes d'être signalés.

Puissent-ils ouvrir les yeux à ses concitoyens sur la nécessité d'avoir recours au système de protection découvert, il y a plus d'un siècle, par le bonhomme Franklin, physicien de génie, dont quelques-uns d'entre eux ont peut-être quelquefois entendu parler.

Le coup de foudre de la Porte-Rabel n'est pas le seul qui ait signalé l'orage du 6 septembre. Le fluide est également tombé à Aube sur la maison de M. Avenel, fabricant de chaussures, et à Saint-Symphorien-des-Bruyères, où elle a brisé une porte d'une écurie faisant partie de la ferme du Hameau et appartenant à M. Lecomte.

Ces deux coups de foudre se trouvaient l'un et l'autre à cinq ou six kilomètres du coup principal que nous avons examiné. On n'a pu préciser l'heure exacte à laquelle les explosions avaient eu lieu. On ignore également si les instruments du télégraphe ont été dérangés, ce qui n'a pu avoir lieu que si le coup de foudre a eu une grande intensité, car les employés auraient pris la précaution de mettre leurs appareils *sur terre* en se retirant.

La veille du jour de l'orage, on prétend avoir aperçu sur la pointe de l'unique paratonnerre de la ville de Laigle une étincelle brillant comme le ferait un feu Saint-Elme et indiquant, par conséquent, l'énergie de la tension électrique à laquelle toute la contrée se trouvait soumise.

Nous renverrons le lecteur à ce que nous avons dit dans nos *Eclairs et Tonnerre* sur les moyens d'employer les paratonnerres à avertir de l'imminence des orages. Mais, en voyant l'indifférence grossière avec laquelle la météorologie officielle a traité une suggestion aussi simple, aussi naturelle, nous ne pouvons nous empêcher de faire remarquer combien il est peu probable que cette observation nouvelle ait le pouvoir qu'il n'ont pas eu ses aînées.

Le paysan chez lequel la foudre est venue prendre ses ébats avait eu l'heureuse idée de placer une assiette sur une chaise à l'entrée de sa demeure. Chacun des visiteurs y mettait son offrande, de sorte que le petit sinistre a pu être réparé sans bourse délier, et est même devenu, pour une pauvre famille, une source de profits.

(1) Phylloxera vient de deux mots grecs dont le premier veut dire « feuille » et le second « sécher. » « Potamos » veut dire « fleuve ». Ce qui permet de comprendre le jeu de mots que nous nous permettons.

Manufacturer Record November 1879

Humbug No. 5.—The Chambers National Lightning Protection Co. of Cincinnati.

A company calling itself the Chambers National Lightning Protection Co. of Cincinnati, Ohio, has lately patented a new method of putting up lightning rods, which is nothing but a confession of ignorance on the part of the patentees in regard to the laws of electricity. This new patent lightning rod consists of a horizontal rod running over the ridge of the building, with a point at each end projecting upward, while it is supported on large glass insulators, and has no connection whatsoever with the ground.

The patentees evidently do not know that a stroke of lightning from a cloud to the earth is nothing but the neutralization of two opposite states of electricity—a positive electric cloud and a negative electric earth, made strongly so by the well established law of mutual induction. Every time the electric spark flies over between the two, a part of the charge becomes neutralized, and this neutralization can only take place by the earth receiving the electricity from the cloud and the cloud receiving the opposite electricity from the earth. Frequently these explosions take place between clouds mutually, as often some clouds are positively charged and others negatively; for this we do not want lightning rods; but when the discharge takes place between the earth and the clouds, and a house, tree, or man happens to be in the path of the discharge, the effects are often very destructive. Now, as an electric current prefers a metallic path, metal being a better conductor than any other substance, it is advantageous to give the lightning such a path, by making a metallic connection between the moist and conducting earth below and any spot above where the lightning is likely to fall in its downward course to the earth. Such a metallic connection is a lightning rod, not the point above, which may even be omitted; neither is it necessary to isolate it from the building with glass supports, as is done by ignorant lightning rod men; on the contrary, it should be connected above with the metal of the roof of the house, so that should the lightning strike the roof, it will find through the rod at the side of the house a ready downward path to the earth, without damaging the building. A good earth connection is the principal thing, upon which the greatest care must be bestowed; this is often neglected, and has proved to have been the cause of the failure of many lightning rods to give the expected protection.

Now this ground connection—this most essential feature of all lightning rods—is intended to be left entirely out by the learned Chambers National Lightning Protection Co. of Cincinnati; not only this, but the lightning rod is isolated. The result must be that if a stroke of lightning strikes such a rod from a cloud say 2,000 feet above the house, and overleaps a space of 2,000 feet through the air, it will also easily overleap the 100 feet or less between this new fashioned patent (so called) lightning rod and the ground, and the house, being in its path, will suffer, and the people in it may suffer also.

There is a journal issued by the Iowa Agricultural College, in which recently Prof. Macombes of that college is seriously questioned as to the possibility of protecting a house against lightning by isolating it on glass legs. How stupid! as if a stroke of lightning which descends from a cloud, perhaps half a mile above the roof of the house, could not overleap the distance below the house to the earth, even if the glass legs were 20 feet high.

Tel Journ Sept 15 1879

Report of the Committee on Atmospheric Electricity in Madeira.

Tele. Journ. Sep 15/79

By Dr. M. Grabham.

Remarkable fluctuations of the electric potential were noticed at the time when the maximum potential is reached, which takes place at 11:30 a.m.; this fluctuation the writer ascribes to masses of cloud on moist air. The daily formation of a thin stratum of cloud during fine calm weather which varies slightly in altitude in accordance with temperature and barometric pressure was described. The electricity below this cloud is always positive and moderately strong. In the cloud itself it is more feeble but of the same sign. Above the cloud at the station where the observation was taken it was very feeble and irregular but always positive. In warmer weather the vapour does not condense into cloud but appears as a blue transparent haze from above, and presents the same electrical indications.

The highest potential was observed upon a rock ninety feet high, a few metres from the shore in the Bay of Funchal.

The thinness of the currents of air constituting sea breezes was demonstrated by flying a kite vertically beyond into the true wind blowing in a contrary direction. Abortive attempts were made to bring down the upper electricity through the tower currents. The electricity of the general north east wind which is identical with the trade wind was found on the heights at the east end to be uniformly moderate and positive.

At the approach of rain-clouds at the termination of a period of fine weather the atmosphere invariably gives increased readings and no negative observations were recorded.

The L'este, a kind of sirocco to which Madeira is occasionally subject, electrically gives no indication of any change whatever except by faint fluctuations about the earth-reading.

During the prevalence of L'este wind, the writer noticed a very highly electrical condition of certain clouds which lie quietly among the mountains, though tossed and tumbled on their upper surfaces; he hopes to be able to connect their forms and immobility with their electrical change.

English Mechanic Nov [illegible] 1879

LIGHTNING-CONDUCTORS.*

THE [illegible] upon which electricians do not agree amongst themselves, but [illegible] of their study has been the cause of so many conflicting opinions as lightning-conductors. If you find two electricians who agree as to the theory of the lightning-conductor, they will in all probability differ completely as to the manner of its application and the dimensions most suitable for a given purpose. The bibliography of the subject is extensive, and includes a number of papers from the most distinguished physicists of the present and the last century; but we doubt whether any practical information of much value is to be obtained by a perusal of the whole library, while the reader would certainly acquire a very confused notion of the subject unless he had already received a preliminary training in the principles. The author of the work before us seems to have felt the need of just such a book as he has produced, and his practical experience in planning out lightning-conductors has enabled him to produce a really useful guide to architects, clergymen, municipal officers, and others upon whom may devolve the duty of protecting public and other buildings from injury by lightning. Mr. Anderson has not given us any pet hypothesis of his own as to the nature of lightning, but has judiciously consulted the works of the best authorities, and has furnished us with a readable history of the lightning-conductor, and probably a correct description of the nature of the effects it is intended to prevent. The practical part of the work is, however, the more valuable portion, as it supplies non-technical readers with information many have desired to obtain. It commences with Chapter V., on Metals as Conductors of Electricity, in which the author has, rather uncharitably, exposed the liability of the most distinguished scientists to make serious errors. The relative conductivity of metals is known nowadays with tolerable accuracy; but the figures given by such as Humphry Davy, Becquerel, Ohm, Lenz, and Pouillet, are in some cases inexplicable. Davy taking copper as a standard at 100, found the conducting power of silver to be 109, and iron 14·6, while Becquerel, adopting the same standard, put silver at 73·5 and iron at 15·8, the comparative similarity in the one case making the discrepancy in the other all the more remarkable. The figures given by Lenz are, however, more noticeable still, for he found silver to have a conducting power of 136 and iron of 17·7, while as if to render the subject more mystifying still, Ohm rated silver at 35·6 and iron at 17·4. Pouillet's figures are: silver 81·3, iron between 15 and 18. It will be seen that while the five distinguished experimenters gave very varying results for silver, as indeed they did also for gold, the figures apportioned to iron agree in a very remarkable manner, and there can be no doubt

* Lightning-conductors: their History, Nature, and Mode of Application. By Richard Anderson, M.S.T.E. London: E. and F. N. Spon.

that by taking iron at 16½ and copper at 100 we have a probably accurate estimate of the relative conductivity of the two metals best adapted for making lightning-conductors. In the chapter on the Character of Lightning and Thunderstorms allusion is made to the statement that Solomon overlaid the Temple within and without with pure gold, and thus, unwittingly perhaps, took the best possible means of preserving the edifice from injury by lightning. According to Josephus, Solomon ordered the whole roof to be ornamented with sharply-pointed and thickly-gilded lancets of iron, presumably to prevent birds settling there and soiling the roof. That these points played an important part in protecting the building there can be little doubt, for all experience has indicated the use of points and large surfaces of metal in the attempt to protect buildings from lightning. The chapter on Inquiries into Lightning Protection is a useful, though necessarily brief, account of experiments and reports hitherto made with the view of obtaining some definite data upon which to work, and that is followed by a chapter recounting the experiments of Sir W. S. Harris. It is not impossible that more has been learnt from the failures of conductors than from a study of the theory of lightning, and there can be little doubt that copper is, all things considered, the best material for conductors. The remarkable discrepancies in the conductive power of metals alluded to above were, in all probability, mainly due to the use of impure samples, for Prof. Matthiessen found that if pure copper were taken as standard 100, best American would be only 92·5; Australian, 88·8; Russian, 59·3; and Spanish Rio Tinto only 14·24. Objections were formerly urged against copper on account of its expense; but a more potent reason for its neglect was the simple fact that a suitable copper conductor could not have been obtained. It is essential that the copper should be as pure as possible, for as it is six or seven times the price of iron, it is advisable to take full advantage of the greater conductive power of the more costly metal, which it will be seen nearly balances the difference in price. So far it may be said that iron and copper are practically equal, but there are two other points to consider, and in both of these copper is by a very long way the superior of iron, viz.: durability and flexibility. We can readily agree with Mr. Anderson, then, that copper is the best material for a lightning conductor, and it is not impossible that the wire ropes made by Newall and Co., which have, we believe, a guaranteed conductivity of 93 per cent. of pure copper, are the most suitable things in the market. Chapter X. describes what has been done at the Hotel de Ville, Brussels, and at Westminster Palace, the former building being probably the best protected of any in the world. It is covered on a plan devised by Professor Melsens, consisting of a perfect net-work of metal with numerous points and ample and perfect earth-contacts. The descriptions of the measures taken to protect these buildings will serve to show what is considered good practice, and the practical details under the head of weathercocks, and descriptive of practice in France and America, will help to make the subject clear. The chapter devoted to an explanation of Newall's system is, however, an epitome of the whole subject, and as numerous examples are given, the reader perceives clearly what is required for a barn, a house, a factory chimney or a church steeple. The system advocated by Melsens, of many small rods, instead of one large one is adopted by Mr. Anderson, but it is tolerably well understood nowadays that advantage should be taken of the presence of any considerable piece of metal in a building to bring it into the circuit of the conductor. Thus a church, for instance, instead of ridge tiles should preferably have a ridge of iron, which could be connected to the conductor, and so save the expense of running a copper rope from end to end. Several illustrations of the arrangement best adapted to special cases are given by the author, who also gives particulars of such minor details as fastenings, which should preferably be copper clamps built into the wall, in the case of a chimney for instance, though simple staples nailed to the wall will do very well in the case of the smaller and larger conductors employed on houses. Not the least interesting portion of the book are the illustrations of the effects of lightning as seen in the case of churches and other buildings that have been injured by lightning, an engraving of the monument to General Baird, on the summit of Tomachaistle, near Crieff, serving as a frontispiece, and an excellent example of the disruptive power of a lightning stroke. The "earth connection," very appropriately, has a whole chapter to its consideration, and there are several engravings showing the most approved methods of insuring that at all times the earth wires shall be capable of distributing the discharge. A chapter urging the necessity for frequent inspection and testing of all lightning conductors, brings the work to a close—a very full bibliography forming an appropriate appendix. The book is well printed on good paper, and will, no doubt, become the standard textbook for use by those who are engaged in erecting lightning-conductors.

79

Reviews.

Lightning Conductors, their History, Nature, and Mode of Application. By Richard Anderson, F.C.S., F.G.S., Member of the Society of Telegraph Engineers. London: E. and F. N. Spon.

Judging from the long list of books and pamphlets dealing more or less with the subject of lightning conductors, and given by Mr. Anderson at the commencement and end of his work, it might be imagined that but little more could be added to the existing stock of knowledge regarding the theory and practical construction of the lightning rod; such, however, is not the case, and Mr. Anderson's excellent new book will really prove a most valuable addition not only to a scientific library but also to the library of every architect or other person concerned in the construction of every kind of building.

The amount of ignorance that exists on the subject of lightning conductors is very great; the means that have existed for obtaining information regarding the same has hitherto been equally great. No good English work, with the exception of the one now before us, has been written. This want has now been supplied, and well supplied, too.

The amount of damage effected by lightning in this country alone is very considerable, and not a year passes but we hear of a large number of buildings being struck and greatly damaged; in some cases the mischief done is irreparable. The destruction of ancient buildings inseparably connected with historical associations is in every case a deplorable disaster, and one which no amount of money will repair. Some of our finest ancient structures—Windsor Castle amongst others—are either totally or insufficiently protected from lightning, and may some day be witnesses to the folly or apathy of those to whom their preservation is practically entrusted. Every possible care is taken to protect such structures from fire, and large sums are spent for the purpose, but the few pounds necessary to erect lightning conductors are either grudged or are not expended from pure ignorance of the importance of the means of protection.

In the commencement of his work, Mr. Anderson has written in an entertaining manner an account of the early discoveries made on the subject of electricity, in the narration of which the name of the immortal Franklin is, of course, prominently noticed; how thoroughly this philsopher grasped the truth of the identity of electricity and lightning is well pointed out, and we see that from the date at which this fact was made manifest, namely, at the middle of the last century, the history of lightning conductors practically commences.

The first lightning conductor ever constructed was set up by Franklin himself at his house in Philadelphia. The spread of the system was at first slow, in Europe notably so; in many cases personal enmity checked the progress; an ignorant priesthood, which scented heresy in an attempt to draw lightning from the clouds, for a long period waged war against the heretical rods, but as time went on, and the protective effects of the rods were seen, the opposition ceased, and the disputes took the form of controversies on the proper terminations to give to the protectors, *i.e.*, whether points or balls were most effective. The controversies ran so high that they resulted in the resignation by Sir John Pringle of the Presidency of the Royal Society. Subsequent experiments proved conclusively the superiority of the pointed conductor.

In Chapter V., Mr. Anderson deals with the subject of metals as conductors of electricity, and he gives tables of the comparative values of the various metals as determined by different physicists; the want of agreement is considerable, though the superiority of copper is in all cases agreed upon.

The conductivity of the material employed for the rods is easily determined previous to the fixing of the same, but after their erection their continuity requires testing to detect faulty joints, &c.; for this purpose Mr. Anderson has designed a simple and handy instrument, which consists of a three-cell battery of low resistance, a galvanometer, and a set of three resistance coils. Five keys are attached to the apparatus; by depressing one key the battery is put through the galvanometer direct, another key closes the circuit through a known resistance, a third key interposes a higher resistance, and a fourth key inserts a resistance of a still greater value,

7 80

LIGHTNING-CONDUCTORS.*

THERE are many points upon which electricians do not agree among themselves, but perhaps no branch of their study has been the cause of so many conflicting opinions as lightning-conductors. If you find two electricians who agree as to the theory of the lightning-conductor, they will in all probability differ completely as to the manner of its application and the dimensions most suitable for a given purpose. The bibliography of the subject is extensive, and includes a number of papers from the most distinguished physicists of the present and the last century; but we doubt whether any practical information of much value is to be obtained by a perusal of the whole library, while the reader would certainly acquire a very confused notion of the subject unless he had already received a preliminary training in the principles. The author of the work before us seems to have felt the need of just such a book as he has produced, and his practical experience in planning out lightning-conductors has enabled him to produce a really useful guide to architects, clergymen, municipal officers, and others upon whom may devolve the duty of protecting public and other buildings from injury by lightning. Mr. Anderson has not given us any pet hypothesis of his own as to the nature of lightning, but has judiciously consulted the works of the best authorities, and has furnished us with a readable history of the lightning-conductor, and probably a correct description of the nature of the effects it is intended to prevent. The practical part of the work is, however, the more v[al]uable portion, as it supplies non-techni[cal] readers with informa[tion] that many have des[ir]ed to obtain. It commences with Chapter V., on Metals as Conductors of Electricity, in which the author has, rather uncharitably, exposed the liability of the most distinguished scientists to make serious errors. The relative conductivity of metals is known nowadays with tolerable accuracy; but the figures given by such as Humphrey Davy, Becquerel, Ohm, Lenz, and Pouillet, are in some cases inexplicable. Davy taking copper as a standard of 100, found the conducting power of silver to be 109, and iron 14·6, while Becquerel, adopting the same standard, put silver at 73·6 and iron at 15·8, the comparative similarity in the one case making the discrepancy in the other all the more remarkable. The figures given by Lenz are, however, more noticeable still, for he found silver to have a conducting power of 136 and iron of 17·7, while as if to render the subject more mystifying still, Ohm rated silver at 35·6 and iron at 17·4. Pouillet's figures are: silver 81·3, iron between 15 and 18. It will be seen that while the five distinguished experimenters gave very varying results for silver, as indeed they did also for gold, the figures apportioned to iron agree in a very remarkable manner, and there can be no doubt that by taking iron at 16½ and copper at 100 we have a probably accurate estimate of the relative conductivity of the two metals best adapted for making lightning-conductors. In the chapter on the Character of Lightning and Thunderstorms allusion is made to the statement that Solomon overlaid the Temple within and without with pure gold, and thus, unwittingly perhaps, took the best possible means of preserving the edifice from injury by lightning. According to Josephus, Solomon ordered the whole roof to be ornamented with sharply-pointed and thickly-gilded lancets of iron, presumably to prevent birds settling there and soiling the roof. That these points played an important part in protecting the building there can be little doubt, for all experience has indicated the use of points and large surfaces of metal in the attempt to protect buildings from lightning. The chapter on Inquiries into Lightning Protection is a useful, though necessarily brief, account of experiments and reports hitherto made with the view of obtaining some definite data upon which to work, and that is followed by a chapter recounting the experiments of Sir W. S. Harris. It is not impossible that more has been learnt from the failures of conductors than from a study of the theory of lightning, and there can be little doubt that copper is, all things considered, the best material for conductors. The remarkable discrepancies in the conductive power of metals alluded to above were, in all probability, mainly due to the use of impure samples, for Prof. Matthiessen found that if pure copper were taken as standard 100, best American would be only 92·5; Australian, 88·8; Russian, 59·3; and Spanish Rio Tinto only 14·24. Objections were formerly urged against copper on account of its expense; but a more potent reason for its neglect was the simple fact that a suitable copper conductor could not have been obtained. It is essential that the copper should be as pure as possible, for as it is six or seven times the price of iron, it is advisable to take full advantage of the greater conductive power of the more costly metal, which it will be seen nearly balances the difference in price. So far it may be said that iron and copper are practically equal, but there are two other points to consider, and in both of these copper is by a very long way the superior of iron, viz.: durability and flexibility. We can readily agree with Mr. Anderson, then, that copper is the best material for a lightning conductor, and it is not impossible that the wire ropes made by Newall and Co., which have, we believe, a guaranteed conductivity of 93 per cent. of pure copper, are the most suitable things in the market. Chapter X. describes what has been done at the Hotel de Ville, Brussels, and at Westminster Palace, the former building being probably the best protected of any in the world. It is covered on a plan devised by Professor Melsens, consisting of a perfect net-work of metal with numerous points and ample and perfect earth-contacts. The descriptions of the measures taken to protect these buildings will serve to show what is considered good practice, and the practical details under the head of weathercocks, and descriptive of practice in France and America, will help to make the subject clear. The chapter devoted to an explanation of Newall's system is, however, an epitome of the whole subject, and as numerous examples are given, the reader perceives clearly what is required for a barn, a house, a factory chimney or a church steeple. The system advocated by Melsens, of many small rods, instead of one large one is adopted by Mr. Anderson, but it is tolerably well understood nowadays that advantage should be taken of the presence of any considerable piece of metal in a building to bring it into the circuit of the conductor. Thus a church, for instance, instead of ridge tiles should preferably have a ridge of iron, which could be connected to the conductor, and so save the expense of running a copper rope from end to end. Several illustrations of the arrangement best adapted to special cases are given by the author, who also gives particulars of such minor details as fastenings, which should preferably be copper clamps built into the wall, in the case of a chimney for instance, though simple staples nailed to the wall will do very well in the case of the smaller and lighter conductors employed on houses. Not the least interesting portion of the book are the illustrations of the effects of lightning as seen in the case of churches and other buildings that have been injured by lightning, an engraving of the monument to General Baird, on the summit of Tomnachaistle, near Crieff, serving as a frontispiece, and an excellent example of the disruptive power of a lightning stroke. The "earth connection," very appropriately, has a whole chapter to its consideration, and there are several engravings showing the most approved methods of insuring that at all times the earth wires shall be capable of distributing the discharge. A chapter urging the necessity for frequent inspection and testing of all lightning conductors, brings the work to a close—a very full bibliography forming an appropriate appendix. The book is well printed on good paper, and will, no doubt, become the standard textbook for use by those who are engaged in erecting lightning-conductors.

ON THE AURORA AND ZODIACAL LIGHT OF MAY 2, 1877.

37

BY HENRY C. LEWIS.

A simultaneous appearance of an aurora and the zodiacal light appeared on this evening, and a comparison between them is here given. The various changes of the aurora are given in detail. A remarkable feature was the formation of a bright streamer which maintained its position relative to the earth for nearly an hour. Meanwhile, the Zodiacal Cone, which was bright early in the evening, had moved past the streamer and passed below the horizon. The streamer had remained, like the great pointer, fixed to the earth, and marking its motion, while the heavens revolved past it. This fact was conclusive evidence of the terrestrial character of the aurora and of the cosmical character of the zodiacal light. Another fact leading to the same conclusion was the character of their spectra. That of the zodiacal light was continuous, and that of the aurora was a line-spectrum—the former is such as would be given by sunlight reflected from matter in space; the latter would be given by an electric discharge through a gas.

GENERAL NOTES. 37

CURIOUS ELECTRIC PHENOMENON.—At about 4.30 P. M. this day a severe thunder storm with a deluge of rain came up from the north-west, and lasted about an hour. At 5.30 my wife was standing at the window watching the receding storm, which still raged in the south, just over Leicester, when she observed, immediately after a double flash of lightning, what seemed like a falling star, or a fire-ball from a rocket, drop out of the black cloud about 25° above the horizon, and descend perpendicularly until lost behind a belt of trees. The same phenomenon was repeated at least a dozen times in fifteen minutes, the lightning flashes following each other very rapidly, and the thunder consisting of short and sharp reports. After nearly every flash a fire-ball descended. These balls appeared to be about one-fifth or one-sixth the diameter of the full moon, blunt and rounded at the bottom, drawn out into a tail above, and leaving a train of light behind them. Their color was mostly whitish, but one was distinctly pink, and the course of one was sharply zig-zagged. They fell at a rate certainly not greater than that of an ordinary shooting star. I have never witnessed a phenomenon of this kind myself, but my wife is a good observer, and I can vouch for the trustworthiness of her report.

Protection from Lightning.

A knight of the olden time, in full armor, was probably as safe from the effects of a thunder storm as if he had a lightning rod continually beside him; and one of the Roman Emperors devised a perfectly secure retreat in a thunder storm in the form of a subterraneous vault of iron. He was probably led to this by thinking of a mode of keeping out missiles, having no notion that a thin shell of soft copper would have been quite as effective as massive iron. But those Emperors who, as Suetonius tells us, wore laurel crowns or seal-skin robes, or descended into underground caves or cellars on the appearance of a thunder storm, were not protected at all. Even in France, where special attention is paid to the protection of buildings from lightning, dangerous accidents have occurred where all proper precautions seemed to have been taken. But on more careful examination it was usually found that some one essential element was wanting. The most common danger seems to lie in fancying that a lightning rod is necessarily properly connected with the earth if it dips into a mass of water. Far from it. A well constructed reservoir full of water is not a good "earth" for a lightning rod. The better the stone work and cement, the less are they fitted for this special purpose, and great mischief has been done by forgetting this.—*Nature.*

The Best Form for Lightning Conductors.

37

THE best form for Lightning Conductors was the subject of a paper read by Mr. W. H. Preece before the British Association at its recent meeting. The point to be determined was whether the lightning conductor should be a solid rod, or tubular, or flat. Some gentlemen—among them Snow Harris, Prof. Henry M. de Meleens and M. Guillemin—advocated strips of extensive surface. It was Faraday's opinion in his lifetime that there was no advantage in tubular or flattened forms, as the surface had nothing to do with the conduction of the electric fluid. Faraday's opinion seemed to be borne out by the experiments of Mr. Preece, which were as follows:

He obtained the use of Dr. De la Rue's magnificent battery, and procured conductors of equal material, length and weight, but differing in form. A condenser charged from 3,400 cells afforded a very powerful source of electricity, more than forty-two micro-farads being thus available to produce an enormous spark. Experiments made by heating and deflagrating wires through the different conductors left no doubt that these discharges do obey the law of Ohm, and it therefore that the additional surface of flat and tubular conductors is of no advantage in their conductivity.

Prof. Osborne Reynolds rather doubted the conclusions of Mr. Preece, on account of our not knowing the conditions under which the electricity passes from the air into the surface of the conductor. Prof. Ayrton thought the experiments should be tried with much greater difference of potential. The 3,000 cells would not produce a free spark of more than 1-40th of an inch long, whereas flashes of lightning might extend over miles.

Mr. Preece, in replying, pointed out that increased surface, though increasing its inductive capacity, did not add to its efficiency, which depended only on its conductivity.

Mr. Preece also communicated an observation on the peculiar behavior of copper wires. Very powerful discharges of electricity were found to increase the conductivity of newly-drawn copper wires by an appreciable percentage. Leaden wires showed no such changes. In the subsequent debate it appeared that the opinion was that the effect of the first current was to anneal the wire.

Correspondence. Sept 25 1880

Protection from Lightning.

To the Editor of the Scientific American:

In your paper of August 28 is an article written by Professor Kirchoff, on connecting lightning rods with gas and water mains, in which, after citing a case of lightning destroying several lengths of cast iron water pipe in Basel, he proceeds to state that if the said pipes had been joined with *lead* instead of pitch, no mechanical effects could have been produced.

That the assumption of Professor K. is not justified by the facts is proved by the following cases:

A church in Terre Haute, Indiana, was struck by lightning, the rod knocked down, after which the electricity followed the gas pipes in the church to the mains in the street, and melted the *lead* joints for upwards of one thousand feet.

Another church in Iowa City, Iowa, received a heavy discharge, which damaged the rod, ran on the gas pipes, and thence to the main, and for a distance of several hundred feet every particle of the *lead* joints was burned out.

Other cases might be cited, but these are sufficient to prove that *lead joints* do not prevent mechanical effects when lightning passes over gas pipes.

Another correspondent, in the same issue of your paper, J. C. M., of Bradford, Pa., writing on the subject of protecting oil tanks from damage by lightning, says:

"We would only be too glad to learn of some method other than the old theory, by which we could protect our property from lightning, as that has been demonstrated beyond a doubt to be a failure. We want information on the subject."

J. C. M. is only one of many thousands seeking such information, and it certainly should be forthcoming from some of our scientists. Of what practical value to the human family has been the vast amount of knowledge accumulated on the subject of atmospheric electricity within the last forty or fifty years? Our scientists have studied its modes of action until all agree upon the laws which govern it; yet, so far as protection from lightning is concerned, this knowledge has not helped us forward one single step. The scientific world has demonstrated clearly, and have taught us by their writings for half a century, that what is known as *electric induction* is a universal mode of electric action.

Scientists have also clearly proved that Franklin knew nothing of this law of electric induction, hence that his theory regarding the action of atmospheric electricity was erroneous. Is it not strange, then, that our scientists should to this day countenance a system of lightning protection (so-called) suggested and recommended by Franklin, and which, by him, was based upon what has been so clearly proved to have been an erroneous theory? Is it reasonable or logical to expect protection from a system founded upon such a basis? Had the great Franklin understood electric induction, his wonderful intuition would have enabled him, without doubt, to suggest the proper method of constructing apparatus for protecting our property from lightning.

Electric induction is theoretically acknowledged and taught by all scientific authorities, yet when the subject of devising some practical system of protection from lightning is under consideration, these same authorities as completely ignore this law of electric induction as did Franklin, who, they prove, knew nothing about it.

Before we can hope for any efficient system of protecting our property from the dire effects of the lightning stroke, it must be clear to inquiring minds that we must no longer ignore this wonderful law of electric action known as electric induction, but must keep it ever before us and recognize it as an all-important and indispensable factor in our investigations. Any other course must result in the future, as it has in the past, in total failure.

ON THE NECESSITY FOR A REGULAR INSPECTION OF LIGHTNING CONDUCTORS.†

BY RICHARD ANDERSON, F.C.S., F.G.S.

One of the most valuable suggestions which has been made in connection with lightning conductors was that by M. W. de Fonvielle in his paper "On the Advantages of Keeping Records of Physical Phenomena connected with Thunderstorms," read before this Association in 1872. In that paper M. de Fonvielle referred to the steps taken by the French Government for having maps drawn of the course followed by thunderstorms; and he reminded the Association that the French Academy of Sciences as far back as 1823 recommended the Government of France to establish a record of cases of damage by lightning to buildings which had been supplied with lightning conductors. He pointed out that the efficiency of lightning conductors had been questioned, and that in Manchester a conference held on the occasion of Kersal Church being struck had arrived at the conclusion that lightning conductors were worse than useless.

Although it was suggested by M. de Fonvielle that this Association should establish some organisation for the collection of such data, no results have, so far as I am aware, been published.
